ABSTRACT: Rawinsonde observations have long been used to estimate the atmospheric boundary layer depth (BLD), which is an important parameter for monitoring air quality, dispersion studies, weather forecast models, and inversion systems for estimating regional surface–atmosphere fluxes of tracers. Although many approaches exist for deriving the BLDs from rawinsonde observations, the bulk Richardson approach has been found to be most appropriate. However, the impact of errors in the measured thermodynamic and kinematic fields on the estimated BLDs remains unexplored. We argue that quantifying BLD error (δ BLD) estimates is equally as important as the BLDs themselves. Here we quantified δ BLD by applying the bulk Richardson method to 35 years of rawinsonde data obtained from three stations in the United States: Sterling, Virginia; Amarillo, Texas; and Salt Lake City, Utah. Results revealed similar features in terms of their respective errors. A -2°C bias in temperature yielded a mean δ BLD ranging from -15 to 200 m. A $+2^{\circ}\text{C}$ bias in temperature yielded a mean δ BLD ranging from -214 to $+18$ m. For a -5% relative humidity bias, the mean δ BLD ranged from -302 to $+7$ m. For a $+5\%$ relative humidity bias, the mean δ BLD ranged from $+2$ to $+249$ m. Differences of $\pm 2\text{ m s}^{-1}$ in the winds yielded BLD errors of $\sim \pm 300$ m. The δ BLD increased as a function of BLD when introducing errors to the thermodynamic fields and decreased as a function of BLD when introducing errors to the kinematic fields. These findings expand upon previous work evaluating rawinsonde-derived δ BLD by quantifying δ BLD arising from rawinsonde-derived thermodynamic and kinematic measurements. Knowledge of δ BLD is critical in, for example, intercomparison studies where rawinsonde-derived BLDs are used as references.

1. Introduction

The depth of Earth's atmospheric boundary layer (ABL) is a critical component for many applications including, e.g., weather and climate models, air quality and dispersion studies, and inversion systems used to estimate regional surface–atmosphere fluxes of tracers. Because the ABL depth (henceforth the BLD) governs the vertical mixing of passive tracers and aerosols, the afternoon BLD is an important variable for many applications. The afternoon BLD represents the maximum height to which surface-based pollutants disperse and thus is essential for studies of, e.g., dispersion of trace gases (e.g., Lee et al. 2018).

Many different platforms are used to determine ABL heights including masts (e.g., San José and Casanova 1988), sodars (e.g., Piringer 1988; Beyrich 1997), atmospheric emitted radiance interferometers (AERIs; e.g., Feltz et al. 1998), ground-based lidars (e.g., Menut et al. 1999; Hennemuth and Lammert 2006), airborne lidars (e.g., Nyeki et al. 2000), satellite-borne lidars (e.g., Winker et al. 2007), and more [see, e.g., Seibert et al. (2000) for a review].

For decades, rawinsonde profiles have been used for obtaining BLDs on a routine basis. Rawinsondes are advantageous in this regard because they are distributed globally. There are currently ~ 1300 upper-air stations, including 92 National Weather Service upper-air stations in the United States. Because of their global coverage, rawinsonde observations have been used to construct regional- to global-scale BLD climatologies (e.g., Holzworth 1964; Liu and Liang 2010; Wang and Wang 2014) and to develop climatologies of the quasi-stationary afternoon BLD over different continents (e.g., Wang and Wang 2014; Lee and Pal 2017). Nonetheless, there remains a significant need for additional BLD observations (e.g., Dabberdt et al. 2005; Hardesty and Hoff 2012; Everett 2018).

Rawinsonde-based approaches for determining BLDs are largely based on the thermodynamic characteristics of the rawinsonde profile, that is, the parcel method (e.g., Holzworth 1964, 1967), the depth of the elevated temperature inversion (e.g., Holzworth 1964), etc.; or using gradients in potential temperature (e.g., Stull 1988; Seidel et al. 2010; Pal 2019), humidity (e.g., von Engel and Teixeira 2013), or refractivity (e.g., Sokolovskiy et al. 2006) [see, e.g., Seidel et al. (2010) for more details]. Of the techniques that can be used to determine the BLD from rawinsondes, the bulk Richardson (Ri_b) approach (Vogelezang and Holtslag 1996), which identifies the BLD as the first height at which a critical value, Ri_c , is exceeded, has been cited as the preferred approach to determine the BLD

TABLE 1. Manufacturer-stated accuracy from commonly used rawinsondes for sampling BLDs.

Instrument	Temperature accuracy	Relative humidity accuracy	Wind speed accuracy
Vaisala radiosonde RS41-SG	0.3°C (<16 km); 0.4°C (>16 km)	4%	0.15 m s ⁻¹
Graw DFM-09 radiosonde	0.2°C	4%	—
Windsonde	0.3°C	2.0%	—
iMet-4 radiosonde	0.5°C (>100 hPa); 1.0°C (<100 hPa)	5%	0.5 m s ⁻¹
iMet-1-ABxn radiosonde	0.2°C	5%	—

(e.g., Seibert et al. 2000; Seidel et al. 2012). Furthermore, the Ri_b approach has been shown to work well in identifying BLDs from large datasets, for example, those from rawinsondes or from model reanalysis (e.g., Seidel et al. 2012) and for daytime convective boundary layers (Seibert et al. 2000), which are the focus of this study. Another advantage of the Ri_b approach is that the approach calculates the BLD not only as a function of the ABL thermodynamics but also as a function of the ABL kinematics (e.g., Lee and De Wekker 2016), the latter of which is important for highly sheared ABLs (e.g., Conzemius and Fedorovich 2006; Fedorovich and Conzemius 2008; Liu et al. 2018). Additionally, large errors in the measured thermodynamic variables oftentimes coincide with drastic changes in the ABL environment. These changes occur in the surface layer or atop the ABL, especially in the entrainment zone in the presence of shear (Connell and Miller 1995; Fedorovich and Conzemius 2008). Since the surface layer and entrainment zone mainly demarcate the ABL, large errors in thermodynamic variables in these regions can induce significant errors in the estimated BLD.

Regardless of how rawinsonde-based BLDs are determined, BLDs are subject to errors caused by instrument errors. Since the BLD represents the height in the atmosphere to which turbulent mixing processes occur, errors in BLD estimates can have significant impacts for, e.g., air quality and dispersion models, numerical weather prediction (NWP) models, and inversion models in which the BLD is used as a scaling factor within the context of similarity theory (e.g., Stull 1988). Errors in rawinsonde-derived thermodynamic parameters arise for many reasons. For example, temperature and relative humidity (RH) errors occur due to solar radiation heating the sensor and causing a dry RH bias (e.g., Dupont et al. 2020), contamination by surface heating prior to launch, and erroneous temperature and pressure initialization (Connell and Miller 1995). Errors in the RH arise due to, e.g., the time response of RH sensor of the sondes, the sensor's dependence on temperature gradients, and its time lag for low temperatures (e.g., Dupont et al. 2020). Errors in rawinsonde-derived wind speed may arise due to the pendulum-type motion of the rawinsonde while the rawinsonde is in the ABL or entrainment zone (e.g., MacCready 1965; Wang et al. 2009). Other BLD errors arise by the technique used to compute the BLD itself. For example, Seidel et al. (2012) found BLD errors on the order of a few hundred meters when examining the sensitivity of Ri_c value used, the interpolation of the Ri_b profile to Ri_c , and the sounding vertical resolution.

Despite the aforementioned studies on BLD errors, to the best of the authors' knowledge, no known studies have systematically examined the sensitivity of the calculated BLDs to errors in temperature, relative humidity, and horizontal wind

measurements made by rawinsondes or have addressed the impact of errors in those variables on BLDs computed using the Ri_b approach. Knowledge of potential errors that may arise is critical for better using BLDs in atmospheric process studies, intercomparisons of BLDs obtained from different platforms, and for other applications including, e.g., air quality and NWP models. For example, Kretschmer et al. (2012) and Pino et al. (2013) reported that the influence of errors in BLD simulations drives large uncertainties in the inverse modeling of regional-scale greenhouse gas fluxes. Tangborn et al. (2020) recently illustrated that BLD assimilation helps improve forecasts of ABL thermodynamic fields.

For most commercially available rawinsondes, the manufacturer-reported uncertainties are quite low and are summarized in Table 1. For example, the Vaisala radiosonde RS41-SG has a manufacturer-reported temperature uncertainty of 0.3°C for observations below 16 km. The uncertainty in the sounding for measured RH from the RS41-SG is 4% and is 0.15 m s⁻¹ for wind speed. Similar levels of uncertainty are reported for other commercially available radiosondes. Additionally, according to the World Meteorological Organization's (WMO) Observation Systems Capability Analysis and Review Tool (OSCAR), which is a critical component of the WMO Integrated Global Observing System (WIGOS), three different requirement levels have been outlined for using observations in numerical simulations. For instance, the threshold level (i.e., the minimum requirement for the usefulness of observations) requirement for temperature, RH, and wind uncertainties for use in high-resolution NWP is 3°C, 10%, and 5 m s⁻¹, respectively. The breakthrough level (i.e., at which there is a significant improvement of an application and that is optimum from a cost-benefit point of view) requirement for temperature, RH, and wind uncertainties for high-resolution NWP is 1°C, 5%, and 2 m s⁻¹, respectively. However, it is unclear how these errors impact the errors in the BLD estimation.

The aim of this work is to better understand how uncertainties in the thermodynamic and kinematic fields obtained from rawinsondes, coupled with the errors induced by other factors described previously (e.g., radiative effects, the rawinsonde's pendulum-type motion, etc.), affect the calculated BLD. To this end, we examine the sensitivity of BLDs to errors in the temperature, moisture, and wind fields over three sites in the continental United States spanning 35 years.

2. Data and methods

We used rawinsonde observations from the Integrated Global Radiosonde Archive (IGRA; e.g., Durre and Yin 2008)

for the period from 1 January 1981 through 31 December 2015 at three sites in the contiguous United States: Sterling, Virginia; Amarillo, Texas; and Salt Lake City, Utah (Table 2). The use of 35 years of rawinsonde-derived BLDs at sites in three different geographic and climatic regimes (i.e., humid subtropical, tropical and subtropical steppe climate, and warm summer continental at Sterling, Amarillo, and Salt Lake City, respectively, based on the Köppen climate classification; Lee and Pal 2017) allowed for a robust investigation of the biases caused by errors in the rawinsonde-derived thermodynamic and kinematic fields.

The IGRA datasets at each site are mostly complete but there are days with missing data. Because of the missing data, BLDs are able to be computed on 81%, 76%, and 74% of the days at Sterling, Amarillo, and Salt Lake City, respectively. We calculated the BLD by first computing Ri_b , whereby bulk gradients are used to approximate local gradients present in the computation of the gradient Richardson number (Ri):

$$Ri = \frac{g \frac{\partial \theta_v}{\partial z}}{\theta_v \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right]} \approx \frac{g \Delta \theta_v \Delta z}{\theta_v [(\Delta u)^2 + (\Delta v)^2]}. \quad (1)$$

In Eq. (1), g , θ_v , z , u and v represent the gravitational acceleration, virtual potential temperature, sampling height, zonal wind component, and meridional wind component, respectively. When calculating the bulk gradients, we used the surface as the lower bound. Because surface wind speeds are not routinely available in sounding databases like IGRA, following Seidel et al. (2012), we used 0 m s^{-1} for the surface wind speeds. We then followed the approach developed by Lee and De Wekker (2016) to estimate the afternoon BLD. Their approach removes near-surface stable layers, i.e., where $\Delta \theta_v > 0$, from the 0000 UTC IGRA rawinsonde observations to determine the depth of the afternoon boundary layer. We defined the depth of the afternoon boundary layer as the first height at which Ri_b exceeded the critical Richardson number Ri_c . Previous studies have used 0.25 for Ri_c (e.g., Vogelesang and Holtlag 1996; Seidel et al. 2012), and sensitivity studies to the choice of Ri_c are reported in, for example, Seidel et al. (2012). Additionally, we defined the BLD as the height of the ABL relative to ground level to remove the effect of terrain elevation on the ABL.

We used the BLDs computed using the above technique to be the “true” BLDs, which we define here as BLD_{obs} , and then evaluated the impact of height-independent errors in temperature, RH, and the zonal and meridional wind components on the BLD. A systematic evaluation of these hypothetical errors in state variables is important because temperature errors in rawinsondes occur due to the temperature sensor’s time constant. These effects become most important in the presence of sharp vertical gradients, such as those occurring atop the ABL and at the secondary inversions beyond the ABL top. In addition to applying errors to the temperature fields, we also applied errors to the rawinsonde-derived RH and wind fields.

In this work, we explore BLD errors occurring due to errors in not only the thermodynamic fields, but also the kinematic fields. We introduced these errors by applying a constant bias to the measured variable at each height in the rawinsonde

TABLE 2. Station name, latitude, longitude, and elevation for the sites considered in this study.

Station name	Lat (°)	Lon (°)	Elev (m)
Sterling	8.98	−77.48	86
Amarillo	35.23	−101.70	1094
Salt Lake City	40.77	−111.97	1288

profile and then iterated this for each incremental perturbation in the error range. For example, when we evaluated the impact that a -3°C temperature bias has on the BLD, we subtracted 3°C from each temperature measurement at each height in the rawinsonde profile, but did not modify any other variables. We then computed the BLD using the modified profile following the approach described earlier.

We introduced height-independent errors of temperature, RH, and horizontal wind (both zonal and meridional components) throughout the entire rawinsonde profile. Considering height-independent errors allows us to examine the impact of both random errors and instrumental errors that persist throughout the lower troposphere (i.e., 5–6 km AGL) but may vary among soundings (WMO 2017, 2018). The introduction of height-dependent errors would cause additional uncertainty, for example, in rawinsonde profiles containing multiple elevated inversions. Additionally, height-dependent errors based on analytical functions can be prone to errors in the surface-layer temperature structure. Furthermore, the development of analytical functions for errors in the thermodynamic variables following the physics of the real ABL is a highly challenging task. We acknowledge that one of the shortcomings of our approach is that we cannot examine the impact of vertical resolutions and smoothing of the thermodynamic and kinematic variables, but acknowledge that the investigation of errors in sounding vertical resolution has already been conducted by Seidel et al. (2012).

For the analyses presented, we introduced the WMO-specified observation-inclusion thresholds as our error ranges (cf. section 1), which are $\pm 3^\circ\text{C}$, $\pm 10\%$, and $\pm 5 \text{ m s}^{-1}$ for temperature, RH, and wind speed, respectively. Also, these levels are the threshold requirements for including observations in high-resolution NWP as mentioned before. To illustrate how we investigated the impact of errors in temperature, RH, and wind, we used the rawinsonde profile obtained on 11 January 2015 profile at Amarillo. To examine the sensitivity of computed BLDs to errors in temperature, we performed sensitivity tests over the range from -3° to $+3^\circ\text{C}$ at 0.1°C increments. When introducing these perturbations to the temperature fields, the humidity and wind fields were not changed. We then used the perturbed temperatures to compute θ_v and calculated the BLD using Eq. (1). Doing so yielded 60 different Ri_b profiles, and thus 60 different BLDs, as illustrated in Figs. 1a and 1b. For instance, the blue region in Fig. 1a represents errors in temperature profile around the “true” profile; however, the vertical spread of the red line indicating ABL top was negligible. Thus, in this instance, modifying the temperature profile by $\pm 3^\circ\text{C}$ had a negligible impact on the BLD. However, it remains unclear how different temperature

FIG. 1. Sensitivity test, using the 0000 UTC 11 Jan 2015 sounding at Amarillo on the impact of (a) temperature biases (blue lines illustrate the error range) on (b) the Ri_b profile (blue lines; not visible because effect is negligible) and the BLD (red lines; again the effect is negligible). (c) The impact of RH errors on (d) the Ri_b profile and BLD. The same analysis is shown for the effect of (e), (f) the u wind component and (g), (h) v wind component. The black lines show the observed rawinsonde profile for each quantity on the x axis [identical in (b), (d), (f), and (h)].

profiles with imposed height-dependent errors, different temperature inversion strengths, entrainment zone structures, different time scales of sensors, different rawinsonde ascent rates, and different ABL regimes under various meteorological conditions, etc. impact errors in retrieved BLDs computed using the Ri_b approach. Thus, one needs to examine errors for many profiles, which we do in the next section.

We used the same rawinsonde profile obtained on 11 January 2015 profile at Amarillo and repeated the sensitivity test for RH, keeping the temperature and wind fields constant, and performed this test over the range from -10% to $+10\%$ at 0.2% increments. The perturbed values for RH were used to compute the specific humidity, q , which was then used to calculate θ_v and to compute the BLD following Eq. (1). The impacts of changing RH are illustrated in Figs. 1c and 1d. As with temperature, varying RH by $\pm 10\%$ did not significantly impact the BLD on this particular day.

We performed similar sensitivity tests for the zonal and meridional wind components over the range from -5 to $+5 \text{ m s}^{-1}$ at 0.1 m s^{-1} increments using these perturbed values in Eq. (1) while keeping the temperature and moisture fields constant. The impact of varying u on the Ri_b profiles is illustrated in Figs. 1e and 1f, and the impact of varying v is shown in Figs. 1g and 1h. On this particular day, variations in u and v had a more significant impact than varying the thermodynamic quantities on the Ri_b profiles and thus led to BLD errors, which we define as δBLD , of $\sim 100 \text{ m}$.

The results obtained using the 11 January 2015 profile at Amarillo help illustrate the methodology of the impact of errors in the state variables on the estimation of BLDs for a

single case. However, it remains unclear how the impact of similar errors emerges for a range of ABL regimes throughout the year under different meteorological conditions (e.g., different seasons). A more detailed analysis on the impact of these errors allows for more generalized conclusions to be drawn and is the focus of the next section.

3. Results and discussion

a. Errors in rawinsonde-derived temperature fields

One of the driving factors behind this work is the application of the results to evaluate errors in BLD measurements for different ABL applications including NWP and BLD inter-comparison efforts. To investigate how these errors affect BLD, we plotted δBLD as a function of the temperature error for all profiles, as was done in the single example profile shown in Fig. 1. We then sorted δBLD into 10-m bins and determined the number of occurrences N within each of these bins to illustrate the spread of δBLD due to imposed temperature errors. Because the number of cases per bin varied significantly, we report $\log_{10}(N)$, rather than the actual number of occurrences. Additionally, we calculated the 2.5th, 5th, 10th, 50th, 90th, 95th, and 97.5th percentiles of δBLD to further illustrate the range of δBLD as a function of errors in the rawinsonde-derived thermodynamic and kinematic fields.

We found that the δBLD from Sterling, Amarillo, and Salt Lake City behaved similarly in terms of their respective biases when inducing an error to the rawinsonde's temperature measurements and then computing the BLDs (Fig. 2).

FIG. 2. Dependence of δBLD on temperature biases from -3°C to $+3^{\circ}\text{C}$ at (a) Sterling, (c) Amarillo, and (e) Salt Lake City. The distribution is shown in $\log_{10}(N)$ scale (see color bar range from 0.25 to 3.75). Here, N is the number of cases each bin, wherein the data are binned every 10 m and every 0.1°C . (b), (d), and (f) show the percentiles at each of the sites, respectively; purple, blue, green, black, orange, red, and brown correspond to the 2.5th, 5th, 10th, 50th, 90th, 95th, and 97.5th percentiles, respectively.

These results indicate that negative and positive biases in temperature mainly yield positive and negative δBLD , respectively. In the extreme case of a $\pm 3^\circ\text{C}$ bias in temperature, BLD errors were $\pm 300\text{ m}$ at the 2.5th and 97.5th percentiles and were similar across all sites. We also noted a few instances at all sites in which δBLD were significantly high, approaching 1000 m in a few circumstances (i.e., Figs. 2a,c,e), and we found that the BLD errors do not linearly vary from negative to positive biases. Thus, a simple analytical correction for these results cannot be applied.

The relationship between temperature biases and δBLD initially appears counterintuitive, since one would expect a positive temperature bias to increase the BLD. However, this is not consistently the case because of how the errors in temperature are propagated to compute Ri_b . When keeping all other variables constant, a change in temperature results in a change to the saturation vapor pressure e_s . We computed e_s using the following equation from Magnus (1844), where T is the air temperature:

$$e_s = 6.1078 \exp\left(\frac{17.269T}{T + 237.3}\right). \quad (2)$$

Because we are keeping RH constant, changing e_s results in a change in the actual vapor pressure e . The change to e results in differences to q , thereby modifying not only θ_v but, more important, modifying the θ_v gradient, affecting Ri_b and thus the computed BLDs.

b. Errors in rawinsonde-derived relative humidity fields

We performed similar analyses for RH as for temperature and found that δBLD was larger for RH errors than for temperature errors (Fig. 3). In the extreme scenario of a -10% RH bias, errors in BLD were up to $500\text{--}700\text{ m}$ at Sterling, Amarillo, and Salt Lake City. In contrast, a $+10\%$ RH bias resulted in errors at the 97.5th percentile of around 500 m at Amarillo and Salt Lake City but around 400 m at Sterling. As was the case with temperature biases, there were instances at all three sites in which δBLD approached 1000 m even for relatively small perturbations to the RH field. A similar argument can be made for the relationship between δBLD and RH bias. Changes in RH result in changes to e , causing q to change. The change in q affected θ_v , thus affecting the θ_v gradient, which altered Ri_b and the computed BLD.

Errors in rawinsonde-derived RH measurements of 5% – 10% in the daytime ABL have been reported in, e.g., Dupont et al. (2020), who attributed RH errors in the lowest 2 km of the ABL to errors in temperature between the temperature measured by the RH sensor itself and the actual air temperature observed by the rawinsonde's temperature sensor. Furthermore, the manufacturer-stated accuracies of many commercially available rawinsondes are on the order of 4% – 5% (cf. Table 1), which does not include, for example, considerations of the sensor's time response when the rawinsonde is ascending through rapidly changing moisture regimes such as those that can occur atop the ABL (e.g., von Engel and Teixeira 2013). As we show here, RH errors of even 4% – 5% can have a significant impact on the calculated BLD.

c. Errors in rawinsonde-derived kinematic fields

So far, we have focused on the impact of errors in the rawinsonde-derived thermodynamic measurements on δBLD , which are important for ABLs governed by buoyancy-driven turbulence. However, we have not yet considered the impact of errors in the rawinsonde-derived kinematic fields. Knowledge of the potential impacts of errors in these fields is especially important for highly sheared ABLs (e.g., Conzemius and Fedorovich 2006; Fedorovich and Conzemius 2008; Liu et al. 2018). Additionally, it has been found that frontal environments pose additional challenges characterizing BLD variability when temperature, moisture and wind change drastically before and after frontal passages (e.g., Boulte et al. 2010; Clark et al. 2020). We found nontrivial BLD errors across all stations when introducing perturbations to the u and v wind components as compared with the thermodynamic quantities. At Sterling, a -5 m s^{-1} bias in the u wind component resulted in δBLD of about 900 m at the 2.5th percentile, and there were a few cases in which δBLD exceed 1000 m (Fig. 4). Errors were smaller at Amarillo and Salt Lake City than at Sterling, but δBLD was still at times $> 500\text{ m}$.

The findings for errors in the u wind component were largely consistent with those for the v wind component (Fig. 5), as δBLD was generally between -500 and $+500\text{ m}$. Unlike for temperature and moisture, there was no clear tendency between negative biases and positive biases, as δBLD was similar for the u and v wind components. As a result, the median δBLD was $\sim 0\text{ m}$. Knowledge of wind-induced errors on BLD is important because, as noted in section 1 and summarized here, the pendulum-like motion of the rawinsonde during its ascent through the ABL can induce errors in the kinematic fields (e.g., MacCready 1965; Wang et al. 2009).

d. Dependence of δBLD on BLD regimes

From the analyses presented in the previous sections of introducing errors to rawinsonde-derived thermodynamic and kinematic fields and then computing the BLD, we conclude that δBLD as a function of the biases that we introduced is similar across all three sites. So far, we have not discussed the different regimes in which δBLD is largest. Doing so is essential because of the different types of BLD variabilities that are routinely observed. For example, shallow and deep BLDs can occur both in the cold and warm seasons (e.g., Liu and Liang 2010; Seidel et al. 2012; Lee and Pal 2017), spatial BLD variability exists for terrain-following versus terrain-independent ABL regimes (e.g., Kalthoff et al. 1998; Kossmann et al. 1998; Lee and De Wekker 2016; Pal et al. 2016), and both shallow and deep BLD regimes can be present during the early-morning (e.g., Lenschow et al. 1979) and early-evening (e.g., Acevedo and Fitzjarrald 2001) transition periods. Furthermore, there are different ABL regimes in which deep versus shallow BLDs prevail, i.e., stable ABLs versus convective ABLs (e.g., Stull 1988), sheared versus nonsheared ABLs (e.g., Fedorovich and Conzemius 2008), cloud-topped versus cloud-free ABLs (e.g., Garratt 1994), moist ABLs versus entrainment-drying ABLs (e.g., Stull 1988), quasi-stationary versus growing ABLs (e.g., Pal and Haefelin 2015;

FIG. 3. As in Fig. 2, but for relative humidity. Data are binned every 10 m and every 0.2%.

Muppa et al. 2016), ABLs over land versus ABLs over water (e.g., Garratt 1994), and rural versus urban ABLs (e.g., Pal et al. 2012).

Because of the many causes of BLD variability, it is critical to investigate the uncertainties in BLDs for shallow versus deep ABLs. To investigate the relationship between δBLD and

BLD_{obs} , we sorted BLD_{obs} into 500-m bins and calculated the BLD errors caused by temperature biases. Here we selected temperature biases $< \pm 3.0^\circ\text{C}$ although we note that our results are not significantly affected by our choice of this threshold, as the trends are present for other thresholds as well based on sensitivity tests using thresholds of $\pm 0.5^\circ$ and $\pm 1.0^\circ\text{C}$

FIG. 4. As in Fig. 2, but for the zonal (i.e., u) wind component. Data are binned every 10 m and every 0.1 m s^{-1} .

(not shown). When using a threshold of $\pm 3^\circ\text{C}$, we found only very small values of δBLD for shallow BLDs (i.e., those $\sim 500 \text{ m}$ AGL). For deep BLDs (i.e., those $> 3000 \text{ m}$ AGL), δBLD ranges from about -300 to about 125 m at the 2.5th and 97.5th percentiles, respectively, as is shown in the

example from Amarillo (Fig. 6a). The relationship between δBLD and BLD is consistent at Sterling and Salt Lake City (not shown).

We found a similar increase in δBLD as a function of BLD when selecting RH biases $< \pm 10\%$, although the magnitude of

FIG. 5. As in Fig. 2, but for the meridional (i.e., v) wind component. Data are binned every 10 m and every 0.1 m s^{-1} .

the errors is larger for deeper BLDs (Fig. 6b). For example, BLDs exceeding 3000 m have errors at the 2.5th and 97.5th percentiles ranging from -500 to -600 m and from $+200$ to $+300$ m, respectively. Sensitivity results for RH biases $< \pm 2.5\%$ and $< \pm 5\%$ (not shown) yielded similar conclusions on the

relationship between δBLD and BLD, and this relationship is consistent with Sterling and Salt Lake City (not shown).

The relationship between δBLD and BLD is less clear when selecting u - and v -wind biases $< \pm 5 \text{ m s}^{-1}$ and plotting δBLD as a function of BLD_{obs} (Figs. 6c,d). In both cases, we found a

FIG. 6. The δ BLD as a function of BLD at Amarillo for (a) temperature biases $< \pm 3^\circ\text{C}$, (b) relative humidity biases $< \pm 10\%$, (c) u -wind-component biases $< \pm 5 \text{ m s}^{-1}$, and (d) v -wind-component biases $< \pm 5 \text{ m s}^{-1}$. Purple, blue, green, black, orange, red, and brown lines correspond to the 2.5th, 5th, 10th, 50th, 90th, 95th, and 97.5th percentiles, respectively. BLD is binned into 500-m bins.

decrease in δ BLD as a function of BLD. For example, BLDs that are $\sim 500 \text{ m}$ have a δ BLD that ranges from ~ -100 to $+400 \text{ m}$ at the 2.5th and 97.5th percentiles, respectively, whereas BLDs that are $\sim 3500 \text{ m}$ have a δ BLD that ranges from ~ -200 to $+150 \text{ m}$ at the 2.5th and 97.5th percentiles, respectively. Sensitivity tests for u - and v -wind biases $< \pm 1$ and $< \pm 3 \text{ m s}^{-1}$, as well as analyses of the other two sites, yielded similar conclusions regarding the relationship between δ BLD and BLD. In the future, we plan to extend these analyses by selecting sheared versus nonsheared ABL

regimes and will investigate the dependencies of u and v errors on δ BLD.

e. Combined effects of errors in the thermodynamic and kinematic fields on δ BLD

So far, we have considered the effects of individual factors on the estimated BLDs separately. However, it is also important to consider the cumulative impact of different factors (i.e., simultaneous uncertainties of temperature, RH, and horizontal wind) on the estimated boundary layer depth. To examine the

FIG. 7. Box-and-whisker plot illustrating the combined effects of biases in temperature, humidity, and wind on δBLD at Amarillo. The boxes encompass the 25th–75th percentiles, the x indicates the 50th percentile, and the whiskers extend out to the 10th and 90th percentiles. Filled circles represent the 2.5th, 5th, 95th, and 97.5th percentiles. The number of cases in each category is shown at the bottom of the figure.

combined effect of different factors on the estimated BLDs, we simultaneously perturbed the temperature, humidity, and wind fields over the entire profile and then recalculated the BLDs as presented via box-and-whisker analyses of δBLD for a range of biases in T , RH , and wind components (Fig. 7). We found that, in the extreme cases (i.e., a temperature, RH , u -wind, and v -wind bias of -3°C , -10% , -5 , and -5 m s^{-1} , respectively), δBLD ranged from about -900 m at the 2.5th percentile to around $+500 \text{ m}$ at the 97.5th percentile, as shown in the example from Amarillo (Fig. 7). At the other extreme (i.e., a temperature, RH , u -wind, and v -wind bias of $+3^{\circ}\text{C}$, $+10\%$, $+5$, and $+5 \text{ m s}^{-1}$, respectively), δBLD ranged from about -200 to 1000 m at the 2.5th and 97.5th percentiles, respectively. These conclusions were consistent at Sterling and Salt Lake City (not shown). Since this is the first time this has been investigated, we are unable to place these results into the context of other studies. Notwithstanding, it became evident once again that the impact of errors of the horizontal wind components (i.e., kinematics) on δBLD is substantial.

f. Mean biases in the rawinsonde-derived thermodynamic and kinematic fields

Averaging the biases across all three sites also allows for us to quantify the expected errors given a known bias in temperature, RH , and wind obtained from rawinsondes. To this end we report the mean δBLD , that is, $\overline{\delta\text{BLD}}$, at the 2.5th and 97.5th percentiles, as 95% of all cases will fall within these bounds. $\overline{\delta\text{BLD}}$ for the thermodynamic fields is summarized in Tables 3 and 4 and highlights the nontrivial errors associated with biased moisture measurements as δBLD was 609 and 483 m for a -10% and $+10\%$ RH bias, respectively. Computing $\overline{\delta\text{BLD}}$ at the 2.5th and 97.5th percentiles also allows us to illustrate the errors present in the u and v wind components

(Table 5), which, when averaged across all three stations, range from -705 to 432 m (from -569 to 591 m) for a -5 m s^{-1} in the u (v) wind component and from -241 to 731 m (from -453 to 634 m) for a $+5 \text{ m s}^{-1}$ in the u (v) wind component.

g. Comparison with previous studies

Our results indicate errors in BLD measurements were similar across different geographic regions and climate regimes. Accordingly, we conclude that our approach for BLD error characterization is universal and can be implied to other sites. Thus, the results provide information on the magnitude of errors in BLD caused by errors in rawinsonde-derived temperature, moisture, and wind fields. We show that these

errors can be nontrivial. The errors that we identify are of similar magnitude to those found by Seidel et al. (2012) in their study of the sensitivity of BLDs computed using the Ri_b approach to several different metrics. In their study, they also used IGRA-derived rawinsonde observations and examined

the sensitivity of BLDs computed using the Ri_b approach to 1) the choice of Ri_c , 2) errors caused by using 0 m s^{-1} for the surface wind speeds, 3) interpolation of the Ri_b profile to Ri_c , and 4) the sounding vertical resolution. The choice of Ri_c and interpolation of the Ri_b profile to Ri_c yielded the smallest errors in BLD. Using values of 0.25 and 0.30 for Ri_c , Seidel et al. (2012) found that uncertainties in the BLD were <50 and $<80 \text{ m}$ at the 50th and 75th percentiles, respectively, whereas interpolation errors yielded BLD uncertainties of ~ 100 and $\sim 150 \text{ m}$ at the 50th and 75th percentiles, respectively. The vertical resolution of the rawinsonde data, as well as errors caused by using 0 m s^{-1} for the surface wind speeds, were nontrivial error sources in the computed BLDs, particularly for shallow ABLs (i.e., ABLs $< 1 \text{ km}$ deep) in which BLD errors were as high as 50% (Seidel et al. 2012). Surface wind speed errors yield BLD errors of ~ 50 – 200 m (~ 200 – 600 m) at the 50th (75th) percentiles (Seidel et al. 2012), which are comparable to the errors we identified in the present work.

4. Summary and concluding remarks

We used 35 years of rawinsonde observations from three sites in the contiguous United States to investigate the impact of errors of thermodynamic and kinematic variables on retrieved BLDs, allowing for a quantitative assessment of the δBLD based on large datasets over land. The thermodynamic and kinematic errors arise due to 1) inherent errors in the rawinsonde measurements themselves based on manufacturer-reported uncertainties, and 2) errors caused by the environment (e.g., radiative effects on the thermodynamic measurements). We found similarities among the three sites, which were located in different geographic and climactic

TABLE 5. Mean 2.5th and 97.5th percentiles of BLD differences over all stations for biases in the u and v wind components, ranging from -5.0 to 5.0 m s^{-1} in increments of 0.5 m s^{-1} .

regimes, when inducing perturbations to the rawinsonde-derived thermodynamic and kinematic fields. For example, for a -2°C ($+2^{\circ}\text{C}$) bias in temperature, δBLD ranged from -15 to 200 m (from -214 to 18 m); for a -5% ($+5\%$) RH bias, $\overline{\delta\text{BLD}}$ ranged from -302 to 7 m (from 2 to 249 m). In the case of a $\pm 2\text{ m s}^{-1}$ bias in the zonal and meridional wind components, BLD errors were around ± 300 m. $\overline{\delta\text{BLD}}$ increased as a function of BLD when introducing errors to the thermodynamic fields, and δBLD decreased as a function of BLD when introducing errors to the kinematic fields.

As the R_i approach is the most widely applicable method for computing BLDs from rawinsonde observations, the findings in this study expand upon previous work quantifying errors in BLDs from rawinsondes (e.g., Seidel et al. 2012; Dupont et al. 2020) by providing a framework to determine the sensitivity and the range of expected BLD errors due to errors in rawinsonde-derived temperature, RH, and wind measurements. This work also proposes a new approach to identify the dependencies of these errors across a range of BLDs that frequently occur due to diverse meteorological conditions.

Furthermore, this work underscores that errors in BLD estimates obtained from rawinsondes are not systematic, which is important because rawinsondes are oftentimes used as the primary source for ABL and upper-air observations. These errors can be problematic when performing BLD climatologies across multiple seasons and for multiple geographic and climatic regions. For this reason, we recommend that, when BLDs from rawinsondes are reported, there also needs to be an uncertainty reported with these values. Utilizing these uncertainties is also important when comparing rawinsonde-derived BLDs with different datasets, including both profile-derived BLDs (i.e., BLDs obtained from lidars, sodars, AERIs, etc.) and BLDs obtained from numerical simulations. In lieu of the quantified errors in δBLD , we recommend using quality flags, providing metadata based on the errors in the thermodynamic variables via routine sensor calibrations on seasonal scales, and/or reporting ascent rates of the rawinsondes over the lower part of the troposphere (e.g., 1.5 times the BLD).

In future work, similar sensitivity analyses as those presented in the present study should be applied to other approaches that can be used for determining BLDs from rawinsondes (e.g., the parcel method, height of the elevated inversion), as well as from other surface-based and remote sensing instruments (water vapor and temperature lidars, microwave radiometers) used to determine the BLD (e.g., Behrendt et al. 2005; Cimini et al. 2013; Dupont et al. 2020). Other future research avenues include the exploration of BLD errors for 1) different atmospheric stability regimes, 2) seasonal changes in surface forcing, 3) complex ABL regimes (e.g., coastal regions, complex terrain, interface of urban-rural regions), and 4) diverse advection regimes (e.g., Pal and Lee 2019a,b; Pal et al. 2020).
