ABSTRACT: We present gravity wave climatologies based on 7 years (2012–18) of lidar and Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) temperatures and reanalysis data at 54° and 69°N in the altitude range 30–70 km. We use 9452 (5044) h of lidar observations at Kühlungsborn [Arctic Lidar Observatory for Middle Atmosphere Research (ALOMAR)]. Filtering according to vertical wavelength ($\lambda_z < 15$ km) or period ($\tau < 8$ h) is applied. Gravity wave potential energy densities (GWPED) per unit volume (E_{pV}) and per unit mass (E_{pm}) are derived. GWPED from reanalysis are smaller compared to lidar. The difference increases with altitude in winter and reaches almost two orders of magnitude around 70 km. A seasonal cycle of E_{pV} with maximum values in winter is present at both stations in nearly all lidar and SABER measurements and in reanalysis data. For SABER and for lidar (with $\lambda < 15$ km) the winter/summer ratios are a factor of ~ 2 –4, but are significantly smaller for lidar with $\tau < 8$ h. The winter/summer ratios are nearly identical at both stations and are significantly larger for E_{pm} compared to E_{pV} . Lidar and SABER observations show that E_{pV} is larger by a factor of ~ 2 at Kühlungsborn compared to ALOMAR, independent of season and altitude. Comparison with mean background winds shows that simple scenarios regarding GW filtering, etc., cannot explain the Kühlungsborn–ALOMAR differences. The value of E_{pV} decreases with altitude in nearly all cases. Corresponding E_{pV} -scale heights from lidar are generally larger in winter compared to summer. Above ~ 55 km, E_{pV} in summer is almost constant with altitude at both stations. The winter–summer difference of E_{pV} scale heights is much smaller or absent in SABER and in reanalysis data.

1. Introduction

It is commonly accepted that gravity waves (GW) play a crucial role in middle-atmospheric circulation, structure, variability, and composition. GW are mainly generated in the troposphere/lower stratosphere by dynamical processes such as convection, wind shears, jet streams, wave–wave interactions, and flows over orographic structures. Upward-propagating GW grow in amplitude due to the exponential decrease of atmospheric air density. During propagation, GW can lose energy and momentum which is referred to as GW breakdown. The energy and momentum lost by GW is deposited in the background flow

which, for example, leads to a mesospheric residual circulation from pole to pole and creates a cold summer mesopause at high latitudes (e.g., Lindzen 1981; Holton 1982; Hitchman et al. 1989; Lübken 1999; Fritts and Alexander 2003; Zhao et al. 2017). It is therefore important to understand the morphology of the GW field and its variation with season and latitude.

Different measurement techniques like satellites (e.g., Hoffmann et al. 2013; Ern et al. 2018), lidars (e.g., Rauthe et al. 2008; Chu et al. 2018), radars (e.g., Hoffmann et al. 2010; Alexander and Murphy 2015; Stober et al. 2021), or balloons (e.g., Allen and Vincent 1995; Hertzog et al. 2008) and rockets (Hirota 1984; Eckermann et al. 1995; Wang et al. 2006) provide detailed information about GW activity in the lower, middle, and upper atmosphere. These techniques cover different height ranges and resolve different fractions of GW spectra in time or space. However, none of them can provide a complete detailed picture. Each measurement technique has its own unique advantages which may enlighten some GW features not seen by other methods. For example, lidars can provide quasi-continuous measurements with high resolution both in time and altitude, thereby allowing for detailed studies of small-scale GW properties. On the other hand, they usually do not provide information about the horizontal distribution of GW.

Unfortunately, it is rather difficult to compare different observations quantitatively. The reason for this is that GW

parameters commonly calculated from measurements are based on deviations from background temperature, density, or winds. Thus, different instruments with different noise level, resolution, temporal and spatial coverage, and background definition will cover different parts of the GW spectrum. A standardized framework for obtaining gravity wave parameters is required to homogenize different studies and to make full use of the information provided by the available measurements (Ehard et al. 2014). Since such framework currently does not exist, global information about the variability of gravity wave activity can be obtained only by satellite observations, however, again with instrumental constraints. More information about observational filters of satellite observations can be found in the literature (see, e.g., Preusse et al. 2008; Alexander et al. 2010; Ern et al. 2018). On the other hand, different instruments covering different spectral windows of the GW spectrum yield complementary observations. The combination of different instruments, e.g., lidar and satellite, usually provide a more detailed picture of GW parameters (Llamedo et al. 2019).

In practice, it is often convenient to have an average reference GW field being representative for a certain latitude and season. Such averaged GW fields, also called climatologies, were published earlier for different locations and altitudes (e.g., Hirota 1984; Tsuda et al. 1994; Whiteway and Carswell 1995; Eckermann 1995b; Rauthe et al. 2008; Baumgarten et al. 2017, hereafter referred to as KB17; Chu et al. 2018; Llamedo et al. 2019). For example, based on one year of lidar observations (1991–92) near Toronto (44°N, 80°W), Whiteway and Carswell (1995) reported that the potential energy in the 35 to 50 km altitude region varied considerably from day to day and seasonally with a winter maximum ($\sim 15 \text{ J kg}^{-1}$) and summer minimum ($\sim 6 \text{ J kg}^{-1}$). Hirota (1984) used meteorological rocket data to obtain the seasonal variation in gravity wave activity in the 30 to 60 km altitude region at a wide range of latitudes. They found an annual cycle with a winter maximum and summer minimum at high and middle latitudes but a semiannual cycle at low latitudes with maxima at the equinoxes. A substantial day-to-day variability was also apparent in these rocket data. Various other measurements generally also demonstrated that the seasonal variation of GW activity in the upper stratosphere and lower mesosphere is dominated by a maximum in winter and a minimum in summer (e.g., Wilson et al. 1991; Rauthe et al. 2008; KB17; Hoffmann et al. 2017; Chu et al. 2018; Llamedo et al. 2019). Some studies also showed a semiannual variation, however, mainly in the upper mesosphere/lower thermosphere (e.g., Tsuda et al. 1994; Mitchell and Beldon 2009; Hoffmann et al. 2010; Chen et al. 2019).

In this study we present the first seasonal cycle of GW potential energy densities (GWPED) in the altitude range 30 to 70 km derived from temperature measurements during the years 2012–18 performed at the Arctic Lidar Observatory for Middle Atmosphere Research (ALOMAR) located in Andenes, northern Norway (69°N, 16°E). We compare with the GWPED seasonal cycle from temperature observations in Kühlungsborn, Germany (54°N, 12°E) in the same altitude range and during the same time period (cf. KB17). Both lidars are daytime capable so that they can be operated during the

whole day if weather conditions permit. This is essential for measuring in polar regions where the Sun is permanently above the horizon during the summer months. We also use satellite-based temperature data from the Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) for comparison with the lidar GW measurements at both locations. Finally, our observations are compared to two widely used reanalysis datasets, namely, NASA Modern-Era Retrospective Analysis for Research and Applications version 2 (MERRA-2) and the fifth generation of ECMWF atmospheric reanalysis of the global climate (ERA5).

The paper is structured as follows. In section 2 the lidar instruments and the observations available at ALOMAR and Kühlungsborn are described, as well as the database from the SABER satellite and the MERRA-2 and ERA5 datasets. In section 3 we present details of the data analysis both for lidar and satellite observations. The main results are presented in sections 4 and 5, followed by a discussion (section 6) and concluding remarks in section 7.

2. Instrumentation

a. ALOMAR lidar

ALOMAR is located in northern Norway (69.3°N, 16.0°E), close to the Scandinavian mountains. A Rayleigh–Mie–Raman (RMR) lidar has been in operation at ALOMAR since 1994. The lidar provides observations of temperatures, winds, aerosols, and noctilucent clouds during day- and nighttime (e.g., von Zahn et al. 2000; Schöch et al. 2008; Fiedler et al. 2011; Baumgarten et al. 2015). Approximately 16 000 h of temperature measurements have been recorded since the start of operation. In this manuscript 5044 h are being used. The lidar consists of two independent power lasers, two receiving telescopes (typically pointing in different directions), and one detection system. The lasers are firing alternately to record the data by the detection system. The raw data are stored with a resolution of 33 s and 50 m. They are integrated in temporal and spatial ranges of 5 min and 150 m altitude, respectively, separately for each of the two telescopes (Baumgarten et al. 2015). The data are further smoothed using a running mean with a width of 2 h and 1 km. Backscattered signals at wavelengths of 532 and 355 nm are used separately to calculate temperature profiles using hydrostatic integration (Hauchecorne and Chanin 1980). Temperatures from both wavelengths and from both telescopes are then combined by calculating the error weighted mean. We have studied the temperature profiles individually for both telescopes which are covering the atmosphere separated horizontally by up to 50 km. No significant difference between the two telescopes was found which is presumably a consequence of the long averaging time. Temperature profiles are available up to 90 km during night and 70 km during day. Data below 30 km are not used in this study due to the sporadic presence of stratospheric aerosols at these altitudes which introduces substantial uncertainties in deriving temperatures (Langenbach et al. 2019).

b. Kühlungsborn lidar

The daylight-capable Rayleigh–Mie–Raman lidar has been installed in Kühlungsborn (54.1°N, 11.8°E) in 2009 and is

operated regularly since summer 2010 (Gerding et al. 2016). About 10 800 h of measurements have been recorded so far. In this paper 9452 h are being used. Similar to the ALOMAR lidar we make use of a flashlamp pumped, injection-seeded neodymium-doped yttrium–aluminum–garnet (Nd:YAG) laser, but transmit only the second harmonic output at 532 nm. The solar background during day is suppressed applying two etalons with full width at half maximum (FWHM) of 4 and 4.5 pm, in combination with a 130 pm interference filter. A narrow field of view of only $\sim 60 \mu\text{rad}$ is applied together with an active beam stabilization on a single-pulse basis. The daylight setup is used also during nighttime to achieve a continuous data stream without technical changes. The raw data are integrated for 2 h with 15 min oversampling, using two detectors with different sensitivities above and below 37 km. Temperature profiles are calculated applying hydrostatic integration. The initial altitude resolution for temperatures is 195 m, which is later downsampled to a 1 km grid. Finally, the data of both detectors are combined to a single temperature profile. Typically, the data cover a similar altitude range as the ALOMAR lidar, namely, up to at least 70 km.

Minor differences between the two lidars in the choice of the start temperatures [taken from NRLMSISE-00 (Picone et al. 2002) or CIRA-86 (Fleming et al. 1990)] and start altitudes for the hydrostatic integrations have only little effects on the results presented here, because this paper mainly deals with temperature fluctuations within 24 h, but not with absolute temperatures.

c. SABER satellite instrument

The SABER instrument is an infrared emission limb sounder covering the upper troposphere, stratosphere, mesosphere, and lower thermosphere. It is one of four instruments on NASA's *Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED)* satellite (e.g., Mlynczak 1997; Russell et al. 1999; Yee et al. 2003). SABER observations started in January 2002 and are still ongoing. SABER temperature observations cover altitudes from below 20 km to well above 90 km with nearly global coverage. The *TIMED* satellite performs yaw cycles such that SABER alternates between a southward and a northward viewing geometry every ~ 60 days. For southward viewing the latitude coverage is about 80°S to 52°N , somewhat depending on altitude, and about 52°S to 80°N for northward viewing. Latitudes between 52°S and 52°N are observed continuously (Remsberg et al. 2008). The vertical resolution of SABER temperature profiles is about 2 km (e.g., Ern et al. 2018, and references therein), which is very close to the vertical field of view of the instrument (Remsberg et al. 2008). SABER temperature observations have repeatedly been used for deriving amplitudes, potential energy densities, as well as absolute momentum fluxes of gravity waves. In this study we use time series of gravity wave potential energy densities for comparison with lidar data. Details on the procedure to extract gravity waves from SABER temperatures, as well as details about the gravity wave datasets used in this study, are given in section 3b.

d. Reanalysis

For comparison we also use the NASA MERRA-2 (Fujiwara et al. 2017) and ERA5 (Hersbach et al. 2020). Both reanalysis

datasets are available on model levels covering altitudes from the ground to about 80 km. Data were extracted at the two locations of the lidar instruments by linear interpolation. MERRA-2 provides data on 72 pressure levels and a horizontal resolution of about 50 km with a time step of 3 h (Global Modeling and Assimilation Office 2015). In global models, sponge layers are commonly applied near the upper boundary to reduce unrealistic reflection of vertically propagating waves from the model top. MERRA-2 implements sponge layers above ~ 0.24 hPa by increasing the horizontal divergence damping coefficient [see Fujiwara et al. (2017) for more details].

ERA5 data are available on 137 levels from the ground to 0.01 hPa with a horizontal resolution of about 30 km and a time step of 1 h (Copernicus Climate Change Service 2017). Sponge layers in ERA5 are applied above 10 hPa by adding an additional function to the horizontal diffusion terms, the strength of which varies with wavenumber and model level (Polichtchouk et al. 2017; Kawatani et al. 2020).

3. Methodology and data description

a. Lidar dataset

We process the lidar data from ALOMAR (69°N) and Kühlungsborn (54°N) by applying the same analysis technique to avoid any biases caused by differences in data processing. Soundings with at least 6 h of continuous measurements were selected, shorter time series are ignored. Measurements that last for more than one day are divided into 24 h segments as in KB17. Within the period from 2012 to 2018 a total number of 5044 and 9452 h have been used from the ALOMAR and Kühlungsborn lidars, respectively. A detailed list of the number of soundings and number of measurement hours are provided in Tables 1 and 2. On average more than 500 h of measurements are available per month, except for December, where the coverage is less than 100 h at both stations. We note that observations are not evenly distributed over the year.

By averaging the data over 2 h and 1 km the effects of small-scale processes like turbulence are eliminated and instrumental noise is suppressed. Temperature errors are derived assuming Poisson noise of the recorded signals and by applying error propagation through all data processing steps. Data points with errors larger than 10 K are excluded from further processing.

Lidar temperatures contain tidal and GW fluctuations on top of a background that contains only slow variations, such as the seasonal cycle or planetary waves. Since we use data blocks shorter than 24 h, the contribution from planetary waves (PW) is removed because they usually have periods of at least a few days (e.g., Kishore et al. 2006).

Figure 1 shows examples of temperature measurements at ALOMAR and Kühlungsborn. Each of these examples contains nearly continuous time series of more than three days (except Kühlungsborn in January, where only 2 days are shown). Remarkable temperature variations are seen throughout the observations in January. For example, at ALOMAR the stratosphere temporarily shows a double maximum at 40 km and

45–50 km. An abrupt change of temperature occurs ~ 10 km higher, where temperatures drop to 190 K around 60 km. At Kühlungsborn a single maximum occurs at around 45 km and successive cold and warm regions of short duration (<4 h) are observed in the lower mesosphere. In contrast, temperatures show less variability in August compared to January at both stations.

1) DERIVING GRAVITY WAVE PERTURBATIONS FROM RAW TEMPERATURES

To extract temperature fluctuations due to GW from lidar observations, the atmospheric background temperature has to be removed. This background consists of a mean temperature profile and a superposition of larger-scale waves, such as PW and tides. Different techniques have been developed to derive this background (e.g., Rauthe et al. 2008; Ehard et al. 2015; KB17; Cai et al. 2017; Chu et al. 2018; Baumgarten and Stober 2019). The easiest and widely applied method for lidar

observations is to use a temporal mean temperature profile (e.g., Gardner et al. 1989; Rauthe et al. 2008; Ehard et al. 2014). In this case the mean temperature profile obviously depends on the averaging time. For example, when subtracting the mean over 24 h, fluctuations still contain contributions from periods of several hours (e.g., from semidiurnal tides) whereas these fluctuations are largely removed when nighttime observations of approximately 5 h duration are being used (e.g., Rauthe et al. 2008). Subtracting a mean profile will also remove any stationary waves thereby underestimating the overall GW activity, because mountain waves will be removed too. Furthermore, semistationary features such as a double-stratopause in Fig. 1a are also removed (e.g., Llamedo et al. 2019).

Various other methods have been developed to separate fluctuations due to gravity waves from the background. For example, Chu et al. (2018) applied a sixth-order Butterworth high-pass filter to remove waves with periods larger than 11 h

FIG. 1. Examples of time–height cross sections of temperatures measured by lidars in (left) January and (right) August at (top) ALOMAR and (bottom) Kühlungsborn.

and vertical wavelengths larger than 30 km. Cai et al. (2017) applied filtering in the time domain where waves with periods of 4, 8, 12, and 24 h were attributed to the background, and the remaining fluctuations to GW. Baumgarten and Stober (2019) used an adaptive spectral filter for lidar measurements, former developed for radar measurements, which takes an intermittency of tides into account. Other studies used a sliding polynomial fitting procedure (Duck et al. 2001; Alexander et al. 2011; Kaifler et al. 2015). Recently, Ehard et al. (2015) evaluated the most common filtering methods applied to lidar observations by using synthetic data. They concluded that the Butterworth filter performs best if gravity waves over a wide range of periods are to be extracted from lidar temperature measurements. The “running mean” method described in Ehard et al. (2015) gave reliable results if gravity waves with short periods are to be analyzed.

Since the purpose of this study is to compare GWPED measured at two different locations, we precisely repeated the procedure applied for Kühlungsborn data in KB17 to the observations at ALOMAR. We define segments with time lengths between 6 and 24 h. Then the temporal mean is subtracted. The results are called “unfiltered data.” By applying a high-pass filter in altitude or time, temperature perturbations with fixed vertical wavelength cutoff altitude or fixed frequency cutoff are retrieved

(Eckermann et al. 1995; Tsuda et al. 2000; Ehard et al. 2015). In more detail we applied a fifth-order Butterworth filter with a cutoff wavelength of $\lambda_z = 15$ km or a cutoff period of $\tau = 8$ h. The choice of $\lambda_z = 15$ km is to assure that semidiurnal tides which have vertical wavelengths of 20 to 100 km are removed (e.g., Davis et al. 2013). Furthermore, a cutoff period of $\tau = 8$ h is sufficient to suppress even the terdiurnal tide. Figure 2 shows a schematic illustration of the difference between vertical and temporal filtering and the particular spectral coverage. The vertically filtered data ($\lambda_z < 15$ km) are also called “small (vertical) wavelengths,” and the temporally filtered data ($\tau < 8$ h) are called “small periods” in this paper. In a former paper we have also applied both spatial and temporal filtering simultaneously (Strelnikova et al. 2020) but this is not done here to be compatible with the data processing procedure used in KB17.

Figure 3 shows temperature fluctuations attributed to GW with $\lambda_z < 15$ km from ALOMAR and Kühlungsborn derived from the temperature fields shown in Fig. 1. At both stations GW signatures are rather different in January compared to August in terms of structure, amplitude, and phase propagation. Fluctuations are considerably larger in winter. In summer, phase lines of a single GW (marked by dashed lines) extend over a larger height range compared to winter. GW

FIG. 2. Schematic illustration of the difference between vertical and temporal filtering. Blue filling represents that part of the data being selected in this study. The red ovals show regions excluded by vertical or temporal filtering. Unfiltered data contain periods from 1 to 24 h and vertical wavelengths from 1 to 40 km.

with upward phase progression are also present occasionally (green dashed lines and negative slopes) but more so in winter than in summer (in summer above 50 km only). Generally speaking, the wave field in summer seems to be dominated by few quasi-monochromatic waves, whereas in winter an ensemble of waves propagating in different directions with different phase speeds is present. When comparing the two locations for the same months, no obvious differences are detectable.

2) GRAVITY WAVE POTENTIAL ENERGY DENSITIES

A widely used physical quantity characterizing GW activity based on temperature fluctuations is the GWPED. There are two forms commonly used, namely, potential energy density per unit mass and per unit volume (see, e.g., Nappo 2002; Gill 1982):

$$E_{pm} = \frac{1}{2} \frac{g^2}{N^2} \overline{\left(\frac{T'}{T_0} \right)^2}, \quad (1)$$

$$E_{pV} = E_{pm} \bar{\rho} = \frac{1}{2} \frac{g^2}{N^2} \overline{\left(\frac{T'}{T_0} \right)^2} \bar{\rho}. \quad (2)$$

Here g is gravitational acceleration, T' and T_0 are residual and background temperatures obtained by the three methods as described in the previous section, $\bar{\rho}$ is the daily average atmospheric density profile taken from NRLMSISE-00 (Picone et al. 2002), and N is the buoyancy (Brunt–Väisälä) frequency derived from measured background temperatures. The overbar denotes a temporal average, which is done over the duration of the measured segment. Usually, temperature fluctuations due to gravity waves increase with altitude because of the decrease of background density. This leads to an increase of E_{pm} with altitude, whereas E_{pV} is constant with height for undisturbed GW propagation at constant winds. We derive

potential energy densities for unfiltered as well as vertically and temporally filtered temperatures for all individual months as well as mean values for summer (June–August) and winter (December–February).

b. SABER data

SABER temperatures are analyzed employing algorithms described in the literature (Preusse et al. 2002; Ern et al. 2011, 2018). To isolate gravity waves from observations, the large-scale background temperature has to be estimated for each temperature profile. For this purpose, 2D spectra in longitude and time are calculated in a set of overlapping 31 day time windows for a set of fixed latitudes and altitudes. From these zonal wavenumber–frequency spectra, the contribution of global-scale waves is reconstructed at the location and time of each observation in every vertical temperature profile observed by SABER. Temperature fluctuations due to gravity waves are obtained by subtracting this contribution of global-scale waves, as well as an estimate of zonally averaged temperatures. This approach removes global-scale waves of zonal wavenumbers 1–6 and waves with periods longer than 1–2 days. Further, we make use of the fact that satellites, measuring at fixed local solar times, observe tides as quasi-stationary wave patterns if ascending (satellite is flying northward) and descending (satellite is flying southward) parts of the orbit are treated separately. All tidal components which appear as stationary planetary waves up to zonal wavenumber 4 (at a fixed given local solar time) are thereby removed. This includes diurnal tides, semidiurnal tides, terdiurnal tides, etc. (Trinh et al. 2018). In addition, the altitude profiles are low-pass filtered to remove very long vertical wavelengths. The resulting residual temperatures are considered to be due to gravity waves. Overall, the SABER gravity wave dataset used in this paper contains gravity waves with horizontal wavelengths larger than about 100–200 km, vertical wavelengths in the range 4–25 km and intrinsic periods longer than 1–2 h [an approximate sensitivity function is given in Ern et al. (2018)]. We use Eq. (2) to calculate E_{pV} based on SABER background temperatures and SABER gravity wave temperature variances.

SABER “local” data presented in this study are gridded for the two specific locations of Kühlungsborn and ALOMAR. For Kühlungsborn, a longitude bin of 5°W–25°E and a latitude bin of 48°–60°N are used. For ALOMAR, we use a longitude bin of 0°–30°E and a latitude bin of 63°–75°N, i.e., the same latitudinal and longitudinal extent as in Kühlungsborn. These SABER time series have a time step of 1 day but we use averages over 5 days in this study, covering the time period 2012–18, as for the lidar data.

c. Gravity wave potential energy densities from reanalysis data

The MERRA-2 and ERA5 datasets were interpolated in time and altitude to provide lidar like altitude profiles that were then analyzed in the same manner as the lidar data. The vertical profiles were interpolated to a fixed altitude spacing of 1 km. We use reanalysis temperatures at ALOMAR and Kühlungsborn. The procedure of calculating GWPED is identical to the lidar data analysis described in section 1 and

FIG. 3. Time–height cross sections of vertically filtered temperature fluctuations ($\lambda_z < 15$ km) in (left) January and (right) August at (top) ALOMAR and (bottom) Kühlungsborn for the same dates as in Fig. 1. Dashed lines mark phase lines where the numbers give the phase progression in km h^{-1} .

section 2. In particular, the reanalysis data are split into segments of 24 h before applying the analysis technique. An example of temperature fluctuations obtained from both datasets is shown in appendix D of this paper.

4. Results

a. Lidar observations

Figure 4 shows individual E_{pV} profiles obtained from vertically filtered data. For this plot 93 (41) winter and 119 (291) summer profiles obtained at ALOMAR (Kühlungsborn) are being used. The profiles are rather variable with altitude, season, and location. Day to day variability is more pronounced in winter than in summer. It turns out that individual values at a given altitude nearly follow a lognormal distribution. We have therefore calculated the standard deviation (σ) of the logarithmic values of E_{pV} for all heights. In the altitude range 30–60 km the standard deviation at ALOMAR is in the range $0.5\text{--}0.6 \log(\text{J m}^{-3})$ for summer and $0.7\text{--}0.85 \log(\text{J m}^{-3})$ for winter. At Kühlungsborn these values are slightly lower, namely, $0.45\text{--}0.55 \log(\text{J m}^{-3})$ in summer and $0.65\text{--}0.8 \log(\text{J m}^{-3})$ in winter. At heights below ~ 60 km the standard deviation does not

show any significant height dependence. Above 60 km σ increases (decreases) slightly with altitude for summer (winter).

The decrease of E_{pV} shown in Fig. 4 is nicely described by an exponential function up to ~ 55 km. We have analyzed this decrease more quantitatively by fitting a function according to

$$E_{pV}(z) = E_{pV}(z_0) \exp\left(-\frac{z - z_0}{H_{pV}}\right). \quad (3)$$

We restrict the fit to the altitude range 30–55 km and derive the scale heights H_{pV} from the fit. The numbers for H_{pV} are provided in the Fig. 4. Generally speaking, E_{pV} decreases less rapidly with altitude in winter than in summer (scale heights are larger in winter). Above approximately 55 km the decrease of E_{pV} with altitude changes compared to below, i.e., the decrease is stronger in winter (but only at ALOMAR) and is weaker (or nearly constant) in summer at both locations. Results of scale heights H_{pV} obtained for appropriate height ranges are demonstrated and discussed in section 6.

We also derived monthly mean values averaged in height bins of 5 km, namely, 35–40, 45–50, and 55–60 km (see also Tables C1 and C2 in appendix C). The results are shown in Fig. 5. In most cases there is a pronounced annual cycle at both

FIG. 4. Vertically filtered E_{pV} profiles observed by lidar in (left) winter and (right) summer at (top) ALOMAR and (bottom) Kühlungsborn. Individual profiles are shown in gray. Thick black lines show mean values. Blue dashed lines mark a constant E_{pV} of 10^{-2} J m^{-3} . Red lines mark linear fits of $\log[E_{pV}(z)]$ where the slopes are given by the equivalent scale heights H_{pV} [see Eq. (3)]. For fitting we used the altitude range 30–55 km. Orange profiles highlight some specific profiles, namely, observations (a) on 10 Feb 2018 at ALOMAR and (c) on 13 Feb 2018 at Kühlungsborn. For conservative propagation E_{pV} would be constant with height, marked here for an arbitrary value of 10^{-2} J m^{-3} (blue dashed line).

locations with maximum in winter and minimum in summer. This result is similar to previous studies of GW activity at other latitudes (e.g., Hirota 1984; Wilson et al. 1991; Whiteway and Carswell 1995; Eckermann 1995b; Rauthe et al. 2008; KB17; Hoffmann et al. 2017; Chu et al. 2018; Llamedo et al. 2019). We note that the situation can be more complex. For example, the seasonal variation is very pronounced for small wavelengths (vertically filtered data) at both locations and in all altitude ranges (Figs. 5b,e), whereas it is much smaller or even absent for small periods (temporally filtered data). Occasionally there are also semiannual variations present in Fig. 5, namely, in the unfiltered data in the altitude range 55–60 km at Kühlungsborn (Fig. 5d) and in the lower altitude ranges (35–40 and 45–50 km) at ALOMAR (Fig. 5a) where minima occur in April/September and secondary maxima in summer. The largest GWPED values are observed in January independent of height range, location, or filtering method. As expected, unfiltered data contain larger GWPED values compared to filtered data (vertically or temporally) since they include a larger portion of the GW spectrum as well as some contributions from tides (see Fig. 2). The results will be discussed in more detail in section 5b.

As can be seen in Fig. 5 nearly all cases reveal a decrease of energy with altitude, as has been shown in detail for the vertically filtered data in Fig. 4. The strongest decrease is observed for small wavelengths (vertically filtered data). To the contrary, GW with small periods (temporally filtered data) show comparatively little variation with altitude: the results for 45–50 and 55–60 km are basically identical.

In Fig. 5g–i the ratios of climatologies obtained at both locations are also shown. E_{pV} from filtered observations (temporally or vertically) are generally larger by a factor of 2 in Kühlungsborn compared to ALOMAR, which is true for all seasons. E_{pV} from unfiltered data (Fig. 5g) are similar in summer in Kühlungsborn and ALOMAR, whereas the difference is again a factor of 2 in winter. It is important to note that the Kühlungsborn/ALOMAR ratios of E_{pV} do not substantially depend on altitude.

We have studied GWPED in more detail by calculating ratios of mean GWPED for winter (DJF) relative to summer (JJA). The results are shown in Fig. 6 as a function of altitude for both stations and for all filtering methods. At both stations, ratios are largest for vertically filtered data (small wavelengths), namely,

FIG. 5. Seasonal cycle of E_{pV} at (a)–(c) ALOMAR and (d)–(f) Khlungsborn at selected altitude ranges: 35–40 km (green), 45–50 km (black), and 55–60 km (red). Each column represents three methods used to calculate E_{pV} : (left) unfiltered, (center) vertically filtered, and (right) temporally filtered. (a)–(f) Shaded regions describe the lognormal standard deviation. (g), (h), (i) The ratios of E_{pV} at Khlungsborn relative to E_{pV} at ALOMAR.

~ 2 – 3 in the lower stratosphere and lower mesosphere with a maximum of roughly 4 around the stratopause. Unfiltered or temporally filtered data show smaller winter/summer ratios, i.e., between 1 and 2–3. Note that winter/summer ratios are close to 1 at the uppermost altitude, independent of location and filtering method. The altitude variation of winter/summer ratios for vertically filtered data can be understood by comparing the GWPED profiles shown in Fig. 4. For example, the decrease of E_{pV} with altitude is weaker in winter (larger-scale heights) compared to summer. Therefore, winter/summer ratios increase with altitude up to ~ 55 km. Above ~ 55 km E_{pV} in summer are almost constant with altitude at both stations, whereas winter values decrease further with height. Therefore, the winter/summer ratios drop above this altitude (see Fig. 6). For the other filtering techniques (vertically and temporally) the variation with altitude is rather similar, although less pronounced.

In Fig. 6 we also show winter/summer ratios for E_{pm} , i.e., for GWPED per unit mass [see Eq. (1)]. Note that all quantities required to calculate E_{pm} are derived from our lidar observations, e.g., $T'(z)$, $T_0(z)$, and $N(z)$. As can be seen in Fig. 6 the winter/summer ratios for E_{pm} are significantly larger compared to E_{pV} both at ALOMAR and at Khlungsborn. This is a consequence of the seasonal variation of temperatures and (for E_{pV}) of mass densities, which vary with altitude and with location. For example, winter/summer ratios of E_{pV} at ALOMAR are smaller than of E_{pm} because mass densities in winter (at a given altitude) are smaller compared to summer.

Note that most climatologies published so far consider E_{pm} (and not E_{pV}) or only temperature fluctuations. There have been theoretical attempts to circumvent this deficiency or to attribute observed differences to the background atmosphere (e.g., Alexander 1998; Eckermann 1995b). If possible, one

FIG. 6. Ratios of mean GWPED in winter (DJF) to summer (JJA) for different cases as observed by lidar. Solid lines are calculated from E_{pV} and dashed lines are calculated from E_{pm} . Blue, red, and green colors are for unfiltered, vertically filtered, and temporally filtered data, respectively. (left) ALOMAR; (right) Kühlungsborn.

should determine GWPED per unit volume (E_{pV}) for comparison, because it accounts for different density, $\rho(z)$, buoyancy frequency, $N(z)$, and temperature profiles, $T(z)$, and it is a conserved quantity in case of undistorted propagation. Since $\rho(z)$, $N(z)$, and $T(z)$ are substantially different in winter compared to summer, E_{pV} instead of E_{pm} should be used to interpret winter/summer ratios of GW activity at different locations in terms of atmospheric processes such as GW sources, filtering, and dissipation. Also variability of $N(z)$ and $T(z)$ reduces winter/summer ratios above ca. 60 km (e.g., Rauthe et al. 2006).

Could it be that our GWPED values in winter are biased because of the occurrence of sudden stratospheric warmings (SSW)? There are some indications that GW activity in the stratosphere/lower mesosphere is rather low because of SSW-related background wind conditions (Ern et al. 2016). Whether, or not, a climatology of GW at a certain station like ALOMAR or Kühlungsborn is affected by SSW depends on several factors. Apart from the fraction of measurements being made during SSW, the location of the station relative to the polar vortex, the strength of the SSW, as well as sources and propagation conditions of GW in the distorted wind field are important. In Fig. 4 individual profiles observed during an SSW in February 2018 are shown at ALOMAR (10 February 2018) and Kühlungsborn (13 February 2018). Obviously, the E_{pV} profiles during these days are not exceptionally small or large compared to other days. Furthermore, we note that the profiles with the smallest values in Fig. 4 were not detected during an SSW. In addition, only a small fraction of the observations in winter took place during an SSW. We conclude that it is rather unlikely that SSW lead to a significant bias of our GWPED climatology in winter. We repeat that a more careful analysis of SSW effects on GWPED is needed taking into account the complicated effects mentioned above. This is beyond the scope of this paper.

b. Results from SABER

Figure 7 gives an overview of the spatial and seasonal variation of E_{pV} at northern middle and high latitudes for winter

and summer at ~ 40 km altitude. Different from lidar, we selected January, February, and March for the winter season (Fig. 7a), and May, June, and July for the summer season (Fig. 7b). This selection is based on poor data coverage at high latitudes in other months which in turn is a consequence of the yaw cycle of the satellite. For a first overview, these data were averaged over 20° in latitude. Figure 7 shows that E_{pV} in winter is approximately 3 times larger than in summer for the whole area. In winter E_{pV} at Kühlungsborn is nearly a factor of 2 larger than at ALOMAR. For summer this difference is smaller, but still, wave activity at middle latitudes is generally larger compared to high latitudes. As can be seen from Fig. 7a there is a substantial variation with longitude of E_{pV} in winter by nearly a factor of 2, both at middle and high latitudes. Moreover, Kühlungsborn is located close to a zonal maximum, whereas ALOMAR is in a minimum. In contrast, in the Alaskan sector the differences between $\sim 55^\circ$ and $\sim 70^\circ$ are very small. The reason for this longitudinal variation of E_{pV} in winter is presumably related to the position of the polar vortex, which is usually slightly shifted to the European sector (e.g., Sato et al. 2009; Ern et al. 2016). A detailed analysis of longitudinal variations of E_{pV} is outside the scope of this paper.

For a more detailed comparison with lidars we select SABER data at the geographic locations of ALOMAR and Kühlungsborn and process the data similar to the lidar observations shown in Fig. 5. The results are shown in Fig. 8 and were derived as described in section 3b. This implies that the spectral range used to obtain the seasonal cycle from SABER is not exactly identical to one of those used for lidars. We therefore cannot expect an exact agreement.

Figure 8 shows E_{pV} averaged over $\pm 6^\circ$ in latitude in the period 2012–18. All available data have been used (solid lines). Since lidars operate only during favorable weather conditions, we extended the comparison by selecting only those days for SABER when lidars were in operation (dashed lines in Fig. 8). As can be seen, the difference is negligible in summer and still less than roughly 20% in winter. Winter months are more sensitive to data selection since the data coverage is worse than in summer and the variability is larger.

FIG. 7. SABER measurements of GWPED per unit volume at 40 km altitude for (left) winter months (January–March) and (right) summer months (May–July) averaged over 7 years (2012–18). The locations of ALOMAR and Kühlungsborn are indicated by symbols “A” and “K,” respectively.

Individual E_{pV} profiles derived from SABER during winter and summer are shown in Fig. 9. Note, that only profiles during dates of lidar observations are considered. In total there are 88 (49) profiles in winter (summer) at ALOMAR and 41 (291) profiles in Kühlungsborn. These profiles exhibit larger variability during winter than in summer, consistent with lidar results. Standard deviations of logarithmic values (σ) are around $0.2 \log(\text{J m}^{-3})$ in summer at both locations and $0.55 \log(\text{J m}^{-3})$ in winter at ALOMAR and $0.45 \log(\text{J m}^{-3})$ in Kühlungsborn. The variability in winter decreases above ~ 60 km. Generally speaking the variability of E_{pV} from SABER is smaller compared to lidar (Figs. 4 and 13). This is perhaps due to different averaging: whereas lidar data are only averaged in time, SABER observations are averaged in time and horizontal distance.

In Fig. 10 ratios of winter to summer values of mean E_{pV} at ALOMAR and Kühlungsborn as derived from SABER (limited to days during lidar operations, separately defined for each location) are shown. Although there is substantial variation with altitude, the profiles of E_{pV} ratios are rather similar for ALOMAR and Kühlungsborn locations. The winter/summer ratio of E_{pV} averaged in the altitude range 30–61 km is equal to

3.7 ± 0.4 at Kühlungsborn and 3.2 ± 0.3 at ALOMAR, i.e., they are identical within error bars. E_{pM} shows larger variability with height. The averaged ratio of E_{pM} is 6 ± 0.8 at Kühlungsborn and ALOMAR. The ratios shown in Fig. 10 are larger when comparing with lidar (Fig. 6), except for vertically filtered data in the altitude range around 55 km, where ratios from lidar are maximal.

c. Results from reanalysis data

The seasonal variation of the vertically filtered E_{pV} at ALOMAR obtained from ERA5 and MERRA-2 in the height bins 35–40, 45–50, and 55–60 km are shown in Fig. 11. We have also applied the other filtering techniques (unfiltered and temporally filtered) and derived a complete set of seasonal E_{pV} variations both for ALOMAR and Kühlungsborn in the three altitude ranges used in this paper. The results are presented in appendix A. As can be seen in Fig. 11 there is basically no seasonal variation of E_{pV} present in ERA5, whereas MERRA-2 reveals a pronounced seasonal variation with maximum values in winter and minimum in summer. A semiannual variation is also present in the uppermost altitude bin (55–60 km) both in ERA5 and MERRA-2.

FIG. 8. Seasonal cycle of E_{pV} from SABER measurements averaged over 7 years (2012–18) at (left) 70°N , 16°E and (center) 54°N , 11°E . (right) The ratio between the locations. The color index is as in Fig. 5. There are no observations at 70°N , 16°E in April and August during the whole 7 yr period. Solid lines are for all available data; dashed lines are for simultaneous observations with lidar.

FIG. 9. As in Fig. 4, but from SABER observations.

As with SABER we used reanalysis data to examine the potential impact of the operational constraints of lidar (clear-sky condition) on the final results. For this purpose we determined monthly mean values from ERA5 using all available profiles and compared the results with days when the lidar was in operation. The same procedure was repeated for MERRA-2. As can be seen in Fig. 11 (dashed lines) the differences are rather small. E_{pV} with preselection of days according to lidar operation are slightly larger, both for ERA5 and MERRA-2, but the differences are generally smaller than the natural variability. We have expanded this analysis by averaging over winter (DJF) and summer (JJA) months. The results are shown in Fig. 12 for vertically filtered data from ERA5 for summer and winter and for both locations. In summer the profiles are practically identical. In winter the restriction in ERA5 to lidar days leads to slightly higher GWPED, but the differences are usually smaller than typically 20%. We conclude that the climatology derived from lidar observations can be considered representative regarding the seasonal variation at these locations. The results are not severely biased because lidar operation is restricted to clear weather conditions.

Regarding the comparison of the two stations, Fig. 11 shows that E_{pV} is generally larger by a factor of 1–2 in Kühlungsborn compared to ALOMAR (for vertically filtered data) in agreement with lidar results (see Fig. 5). Exceptions from this rule are mainly present during the winter months (both in ERA5 and MERRA-2) in particular in the lowest height bin (35–40 km).

5. Comparison

A summary of all E_{pV} profiles, including lidar, SABER, and reanalysis is presented in appendix B. We note that more than 324 combinations of observations can be compared, namely, 2 stations, 3 instruments, 3 filter methods, 2 seasons, 3 altitude

FIG. 10. Winter/summer ratios of mean GWPED obtained from SABER. Solid lines are for E_{pV} , and dashed lines are for E_{pm} . Blue is for ALOMAR, and red is for Kühlungsborn.

FIG. 11. (top) Seasonal cycle of GWPED (E_{pV}) obtained from (left) ERA5 and (right) MERRA-2 data for vertically filtered data at ALOMAR. Solid lines are for all available data; dashed lines are for days with lidar observations. Shaded regions show the standard deviations. (bottom) The ratios of E_{pV} at Kühlungsborn to E_{pV} at ALOMAR. The blue dashed lines represent a ratio of 1. Colors indicate selected altitude ranges: 35–40 km (green), 45–50 km (black), and 55–60 km (red). Note the different scales on the Y axis compare to Figs. 5 and 8.

ranges, and 3 parameters (E_{pV} , E_{pm} , H_{pV}). Here we focus on some selected aspects of a comparison between individual instruments, filtering techniques, seasons, locations, and height profiles.

When comparing SABER with lidar, several observational effects may cause differences that need to be taken into account. For example, the temporal and spatial sampling is different for both methods. Regarding SABER, the results for ALOMAR could be biased during months when the observation geometry changes between northward and southward because SABER does not cover high latitudes for the full month. This would affect the results in January, March, May, July, September, and November. Furthermore, results from SABER are derived by averaging over a horizontal range which is much larger compared to the field of view of the lidars. This can be important in regions where local gravity wave sources are to be expected, like the Scandinavian mountains close to ALOMAR. Regarding lidar, we can presumably rule out a bias due to restrictions to clear-sky conditions (see discussion in section 4c). Taking these potential shortcomings into account, the results obtained by SABER and lidars are generally speaking in good agreement.

a. Vertical profiles of E_{pV} at Kühlungsborn and ALOMAR

Lidar observations show larger E_{pV} in Kühlungsborn compared to ALOMAR, which is consistent with the differences between both stations derived from SABER. We note that this difference is somewhat smaller in SABER compared to lidar. This is presumably an effect of latitudinal averaging in SABER.

In Fig. 13 vertical profiles of E_{pV} from SABER are compared with lidar applying all three filter methods described in section 1. Nearly all profiles show a decrease of E_{pV} with height, except for summer above ~ 55 km where values are nearly constant or even increase with height. We will study this case in more detail in section 6 when comparing with background winds. As expected, both filtering methods ($\lambda_z < 15$ km and $\tau < 8$ h) significantly reduce E_{pV} at all altitudes and at both stations since filtering removes a substantial part of the gravity and tidal wave spectrum.

FIG. 12. Profiles of E_{pV} obtained from vertically filtered ERA5 data. Solid lines are for all data; dashed are for days with lidar observations only.

FIG. 13. Profiles of E_{pV} observed by lidar (solid lines) and SABER (dashed lines) for (left) winter and (right) summer at (top) ALOMAR and (bottom) Kühlungsborn. Black, green, and blue colors indicate different filtering methods. Standard deviations of logarithmic values (σ) are shown as error bars.

In Fig. 14 altitude profiles of ratios of E_{pV} from SABER relative to lidar are shown. The values of E_{pV} from vertically filtered lidar data are rather close to SABER and are sometimes nearly identical, for example below ~ 45 km in summer at both stations. We recall that the data processing applied for SABER removes all waves with large periods (>1 – 2 days) and waves with zonal wavenumbers up to six which corresponds to horizontal wavelengths of roughly $\lambda_x \sim 3300$ km for 60°N . SABER data used here contain vertical wavelengths in the range 4 to 25 km. In summary, SABER covers wavelengths in the range $200 < \lambda_x < 3300$ km, $4 < \lambda_z < 25$ km, and lidars (vertically filtered) cover wavelengths $10 \text{ km} < \lambda_x < \text{several thousand kilometers}$, $\lambda_z < 15$ km. The fact that E_{pV} from lidar (vertically filtered) and SABER are so close to each other implies that E_{pV} outside the common horizontal/vertical wavelength range are either nearly equal or negligible. We note that GW with λ_z between 1 and 15 km and λ_x of several hundred kilometers propagate very obliquely (phase propagation close to the horizon). As can also be seen in Fig. 14 E_{pV} from SABER is generally larger compared to lidar if temporal filtering ($\tau < 8$ h) is applied, and smaller if no filtering is applied.

A comparison of E_{pV} from reanalysis and lidar is shown in Fig. 15. We concentrate on vertically filtered lidar data ($\lambda_z < 15$ km) since some systematic effects are most pronounced here. A complete set of comparisons is presented in appendix B. As can be seen from Fig. 15, E_{pV} from ERA5 and MERRA-2

are generally smaller compared to lidar where the difference increases with altitude in winter and reaches up to two orders of magnitude around 70 km. In summer the situation is more complicated. The values of E_{pV} from ERA5 agree roughly with lidar up to ~ 50 km, whereas MERRA-2 is smaller than lidar by approximately one order of magnitude in the same altitude range. Above ~ 50 km (in summer) it is the other way around: the difference between lidar and reanalysis is larger for ERA5 and smaller for MERRA-2. The spatial resolution in MERRA-2 is worse compared to ERA5 (see section 2d). This presumably explains why E_{pV} from MERRA-2 are generally smaller compared to ERA5. On the other hand, damping in ERA5 increases more rapidly with altitude compared to MERRA-2 which explains why E_{pV} from ERA5 are smaller compared to MERRA-2 above ~ 50 km (see, e.g., Copernicus Climate Change Service 2017; Global Modeling and Assimilation Office 2015).

b. Seasonal variation of E_{pV}

The values of E_{pV} from lidar (Fig. 5) and SABER (Fig. 8) both show a variation with season with minimum values in summer and maximum in winter at both locations and in all altitude ranges. The seasonal variation of E_{pV} from SABER at both locations is somewhat larger compared to lidar (see Figs. 6 and 10).

GWPED from SABER show a weak secondary maximum in summer in Kühlungsborn (a similar analysis cannot be made at

FIG. 14. Ratios of E_{pV} from SABER relative to lidar for (left) winter and (right) summer at (top) ALOMAR and (bottom) Kühlungsborn. Colors indicate different filtering methods (see key).

ALOMAR because the data coverage by SABER is too poor). The unfiltered lidar data shown in Figs. 5a and 5d confirm this increase in the summer months at both stations. This increased activity is absent in the filtered lidar data (both filters and all altitudes, Figs. 5b,c,e,f). Could it be that the summer increase is due to tidal fluctuations in the unfiltered data? Diurnal tides show comparatively small variation with season at middle and high latitudes and at the relevant altitudes (e.g., Gan et al. 2014). Forbes and Wu (2006) reported largest amplitude of ~ 5 K for the westward-propagating semidiurnal tide with zonal wavenumber 2 (SW2) at 60 km and an amplitude of 6 K for stationary planetary waves (SPW1) in winter, and 1–2 K for

both components in summer. There are no indications for a significant semiannual cycle or higher harmonics. The unfiltered data could include some contribution from these tides. However, according to Forbes and Wu (2006) and Pancheva and Mukhtarov (2011) this contribution should be largest in winter which contradicts our comparison between SABER and unfiltered lidar measurements because the difference between SABER and lidar is larger in summer compared to winter at both locations. Our results suggest that a more detailed understanding of GW and tidal spectra and their seasonal variation as a function of wavelengths and frequencies is required to better understand the winter–summer difference.

FIG. 15. Ratios of E_{pV} obtained from reanalysis data relative to lidar for vertically filtered data. (left) Winter months (DJF); (right) summer months (JJA). Solid lines are results from ERA5; dashed lines are from MERRA-2. Black is for ALOMAR; red is for Kühlungsborn.

Regarding the comparison of E_{pV} from reanalysis (ERA5 and MERRA-2) with lidar and SABER we have seen that MERRA-2 qualitatively reproduces the seasonal variation measured by lidars, namely, larger values in winter compared to summer for unfiltered and vertically filtered data, and basically no variation for temporally filtered E_{pV} . There is basically no seasonal variation for the vertically and temporally filtered data in ERA5.

c. Variation of E_{pV} with altitude

In this section we present more details on the exponential decrease of E_{pV} noted in Figs. 4 and 9 for vertically filtered data from lidar and also from SABER. We repeat that E_{pV} would be constant with altitude for undisturbed wave propagation with constant background wind. A decrease of E_{pV} with altitude implies that energy is removed from the GW field. Processes other than dissipation could contribute to the energy removal, for example, wave reflection or refraction or a shift of wavelengths or periods to values outside our filtering window. We characterize the altitude decrease of E_{pV} more quantitatively by fitting an exponential function according to Eq. (3) and derive the scale height H_{pV} from the fit. As can be seen in Fig. 13 a simple exponential decrease is well defined in certain height regions but is not appropriate in others. We therefore constrained the fitting procedure to certain altitude regions (see Table 3).

In the winter–summer comparison we concentrate on altitudes below ~ 60 km since in summer E_{pV} is increasing (not decreasing) above this height. Scale heights H_{pV} deduced from lidar are generally larger in winter compared to summer. This is true for all filtering techniques and both stations, except for unfiltered data in Kühlungsborn. For example, regarding temporally filtered data, we derive $H_{pV} = 31.1$ km and $H_{pV} = 34.1$ km in winter at ALOMAR and Kühlungsborn, respectively, whereas $H_{pV} = 17.4$ and 17.1 km in summer at these stations. In other words, the loss of gravity wave potential energy density with altitude is generally stronger in summer compared to winter. This observational result will be discussed in more detail in section 6 in connection with the background wind profiles.

We have checked if the shape of the density profiles taken from MSISE can affect the shape of the E_{pV} profiles. For this purpose we repeated the analysis with the density profiles measured by the lidar. The differences are less than 10% in most of the altitudes and do not influence our results.

For SABER, the winter–summer comparison is more complex but the difference is generally smaller compared to lidar. For example, at ALOMAR below 60 km, the scale heights are nearly identical in winter and summer. In Kühlungsborn the difference varies with altitude. Regarding the scale heights from SABER compared to lidar, the situation is rather complex. The values of H_{pV} from SABER can be larger or smaller, depending on the station and the filtering method used for lidar. There is one exception, namely, winter in Kühlungsborn, where H_{pV} from SABER is smaller compared to lidar for all filtering methods. In this case GWPED decreases more rapidly with altitude for

TABLE 3. Obtained scale height H_{pV} from lidar and SABER observations for different altitude ranges.

Station	Season	Method	Altitude range (km)	H_{pV} (km)

			61–70	–12

SABER compared to lidar data regardless of filtering method. This indicates that different parts of the GW spectrum dissipate at different heights. We have also calculated H_{pV} from ERA5 and MERRA-2. As expected, the energy-scale heights are much smaller than in observations, as exemplarily indicated in the GWPED ratio in Fig. 15. More details can be found in appendix B. In other words, E_{pV} in ERA5 and MERRA-2 decreases significantly stronger with altitude compared to observations. We note that this decrease is to a large extent determined by technical specifications in the models, e.g., by damping coefficients.

6. Discussion

a. General remarks

In this section we discuss some of the results presented above in relationship to background winds. The concept that GW cannot pass a height region where the horizontal phase

FIG. 16. Mean zonal winds obtained from ECMWF for days when the lidars were operating. (left) Winter season; (right) summer season. Blue is for ALOMAR; red is for Kühlungsborn. Error bars show standard deviations.

speed of GW equals the background wind velocity is a standard mechanism used to explain the winter–summer difference of GW forcing (e.g., Lindzen 1981; Whiteway and Duck 1999; Espy et al. 2004; Jiang et al. 2013). Furthermore, background winds cause a Doppler shift of wave parameters, e.g., of vertical wavelengths and wave periods (e.g., Fritts 1984; Eckermann 1995a; Alexander 1998):

$$\frac{1}{k_z^2} = \left(\frac{\lambda_z}{2\pi} \right)^2 = \left(\frac{v_{\phi,x} - \bar{u}}{N} \right)^2 = \left(\frac{\hat{v}_{\phi,x}}{N} \right)^2, \quad (4)$$

$$\tau_{\text{ground}} = \tau_{\text{intrinsic}} \times \left(\frac{\hat{v}_{\phi,x}}{\bar{u} + \hat{v}_{\phi,x}} \right), \quad (5)$$

where $\hat{v}_{\phi,x}$ and $v_{\phi,x}$ are the intrinsic and ground-based horizontal phase speeds of the GW, k_z and λ_z are vertical wave-number and wavelength, respectively, N is the Brunt–Väisälä frequency, $\bar{u}$ is the mean zonal wind, and τ_{ground} and $\tau_{\text{intrinsic}}$ are the periods observed at the ground and in a system moving with the background wind, respectively.

Generally speaking, GW detected by lidars or SABER are impacted by background winds, for example, by dissipation or by Doppler shifting. We therefore use winds from ECMWF for days when the lidars were operating and calculate mean profiles for both stations and for summer and winter (Fig. 16). A difference between both stations is rather prominent in winter above ~ 30 km: zonal winds are stronger in Kühlungsborn compared to ALOMAR. This is presumably related to the geographic position of the polar night jet. The position of this jet is highly variable and is often shifted southward in the European sector, i.e., toward Kühlungsborn. Comparison of stratospheric zonal winds in Kühlungsborn and ALOMAR suggest that the polar night jet was on average located closer to Kühlungsborn than to ALOMAR, considering days of lidar observations only. We note that the wind situation can be more complicated, in particular during SSW. However, we have seen

already in section 4a that SSW most likely do not cause a significant bias in our GWPED climatology.

b. ALOMAR versus Kühlungsborn: Filtering?

Our lidar observations show that GWPED at Kühlungsborn is larger compared to ALOMAR, especially during winter (Fig. 5). This result is confirmed by SABER (see Fig. 8), but not by MERRA-2 and ERA5 (Fig. 11). Can this difference be explained by filtering or Doppler shifting? Gravity waves cannot propagate further upward if they encounter a region where $v_{\phi,x} = \bar{u}$ [$\lambda_z = 0$ km, see Eq. (4)]. We would therefore expect that in winter filtering by zonal winds is stronger in Kühlungsborn than at ALOMAR because the range of winds encountered by GW on their way from the troposphere to the middle stratosphere is larger in Kühlungsborn (see Fig. 16). In this simple scenario one would therefore expect smaller GWPED in Kühlungsborn compared to ALOMAR, in particular at altitudes above the wind maximum at ~ 40 km. Our observations show the opposite, namely, larger GWPED in Kühlungsborn compared to ALOMAR, also at higher altitudes (see Fig. 5).

If Doppler shifting of GW is sufficiently strong, gravity waves could be shifted to wavelengths or periods which are outside the spectral region covered by vertical or temporal filtering, respectively. Of course, GW can also be shifted into the filtering windows. If, or not, this effect is relevant in our case depends on the source spectrum, the phase speeds of the waves, and the magnitude of the winds. For example, the vertical wavelength of a GW with $v_{\phi,x} = 0 \text{ m s}^{-1}$ increases by 15 km if the background winds increases by 48 m s^{-1} . Another example: the period of a GW with a phase speed of $v_{\phi,x} = -7 \text{ m s}^{-1}$ decreases by a factor of 4.7 in a background wind of $\bar{u} = 40 \text{ m s}^{-1}$ (maximum $\bar{u}$ at ALOMAR). The period of the same wave decreases by a factor of 9.7 if $\bar{u} = 75 \text{ m s}^{-1}$ (maximum $\bar{u}$ at Kühlungsborn). These examples show that Doppler shifting indeed needs to be considered for winds in the winter mesosphere at both stations.

It is tempting to explain larger GWPED in Kühlungsborn compared to ALOMAR for temporally filtered data (lidar) by Doppler shifting since a larger part of GW with large periods (which are expected to have large GWPED) is shifted into the filtering window if background winds are larger (see numbers from above). However, the Kühlungsborn–ALOMAR difference is also present for vertically filtered data (covering all periods), and the difference is also present where the wind difference is much smaller, namely, at altitudes above ~ 60 km (see Fig. 5). Regarding Doppler shifting of λ_z , it is again unlikely that this can explain the Kühlungsborn–ALOMAR difference in winter since Doppler shifting increases with increasing background velocities. Since maximum zonal winds are larger in Kühlungsborn compared to ALOMAR one would expect a larger loss for the former and therefore less GWPED. The opposite is observed. Regarding vertical wavelength, λ_z , GWPED from very small λ_z (less than 1 km) are Doppler-shifted into the spectral window. However, power spectral densities at these small λ_z (large k_z) are presumably very small. In summary, the observational fact that GWPED in Kühlungsborn is larger compared to ALOMAR (independent of the filtering method) cannot easily be explained by the Doppler shifting hypothesis.

Could simple saturation considerations explain the Kühlungsborn–ALOMAR difference? As can be seen from Eq. (4) the vertical wavelength increases if the difference between the phase speed and the background wind increases. Larger vertical wavelengths are associated with more stable propagation conditions. This concept was used to derive a simple condition for gravity wave saturation applying the convective instability limit criterium (Fritts 1984). This results in a condition for the maximum zonal wind fluctuation, namely, $|u'_{\max}| = |v_{\phi,x} - \bar{u}|$. Applying polarization relations for GW results in an equivalent condition for maximum temperature fluctuations, namely,

$$\left| \frac{T'_{\max}}{\bar{T}} \right| = \frac{N^2}{g} \frac{m}{k_x \hat{\omega}} \left| \frac{\hat{\omega}^2 - f^2}{N^2 - \hat{\omega}^2} \right| |v_{\phi,x} - \bar{u}|$$

$$\approx \frac{N}{g} |v_{\phi,x} - \bar{u}| \quad \text{if } N \gg \hat{\omega} \gg f. \quad (6)$$

If we assume, for example, GW with zero phase speeds (note that only GW with negative and zero phase speeds can propagate into the middle stratosphere) in a background wind of 75 and 40 m s^{-1} at Kühlungsborn and ALOMAR, respectively, this would allow maximum temperature fluctuations of roughly $T'_{\max} = 37 \text{ K}$ and $T'_{\max} = 20 \text{ K}$ at these stations. This implies that maximum temperature fluctuations according to the convective instability limit are indeed larger in Kühlungsborn compared to ALOMAR. However, the magnitude of these fluctuations is much larger compared to observations (see Fig. 3). We note that T' is significantly smaller if GW with large periods are considered, i.e., if f^2 can no longer be ignored relative to $\hat{\omega}^2$ in Eq. (6).

Another possibility is that GWs can start to dissipate well before reaching the saturation amplitude (e.g., Achatz 2007). Therefore the difference in saturation amplitudes could still play a role because GWs of the same amplitude would be “closer to saturation” at ALOMAR than at Kühlungsborn.

c. ALOMAR versus Kühlungsborn: Sources?

One could speculate that GW sources are different at both stations. Indeed, ALOMAR is located near the Scandinavian mountains, whereas there are no mountains anywhere close to Kühlungsborn. Simply speaking, this would suggest stronger GW activity at ALOMAR compared to Kühlungsborn, which, however, is not confirmed by our SABER observations. Note that mountain waves are not included in the lidar dataset.

We note that simple scenarios regarding filtering of GW, Doppler shifting, and GW sources do not explain that E_{pV} is larger in Kühlungsborn compared to ALOMAR. This implies that simple GW parameterizations based on the idea of Lindzen (1981) will most likely not be able to explain the latitudinal difference of GWPED in winter. More complicated scenarios are therefore likely. For example, it is known that GW can propagate large distances (several thousand kilometers) away from their source region and they are refracted at horizontal inhomogeneities of the large-scale background (e.g., Eckermann and Vincent 1989; Alexander 1998; Sato et al. 2009; Achatz et al. 2012; Suzuki et al. 2013; Krisch et al. 2017). This implies that local tropospheric GW sources perhaps play a minor role in this context. We note that some studies have indicated stronger wave activity at the edges of the polar vortex, i.e., closer to Kühlungsborn than to ALOMAR which is presumably related to horizontal propagation of GW from lower latitudes toward the polar vortex (e.g., Whiteway and Carswell 1995; Whiteway and Duck 1999; Duck et al. 2001; Ern et al. 2011, 2018; Llamedo et al. 2019). Furthermore, simulations of GW have shown that a time varying background will substantially modify the propagation conditions for GW and that generation of secondary gravity waves is presumably important (see, e.g., Senf and Achatz 2011; Becker and Vadas 2018). A comprehensive discussion and explanation of the Kühlungsborn–ALOMAR difference would need sophisticated modeling including various GW sources, horizontal propagation, and a time-dependent background wind.

d. Winter–summer differences

It is generally accepted that GW activity in the middle atmosphere is stronger in winter compared to summer. This is generally confirmed by lidar and SABER observations presented in this paper (Figs. 6 and 10). Details depend on which part of the spectrum is considered. The winter/summer ratios in ERA5 and MERRA-2 very much depend on the filtering method being applied. For small periods ($\tau < 8$ h, temporally filtered) winter and summer values are nearly identical, for both ERA5 and MERRA-2, and also at both stations. For unfiltered and vertically filtered data, the winter/summer ratios are larger in ERA5 (1:6) and even larger in MERRA-2 (1:10), where winter/summer ratios decrease with altitude.

The standard explanation of the fact that GWPED in winter are larger compared to summer is based on the filtering of GW by the background winds, assuming that the distribution of GW phase speeds is concentrated around $v_{\phi,x} = 0 \text{ m s}^{-1}$. In winter, all GW with negative phase speeds can propagate from lower altitudes to the middle atmosphere, whereas in summer, all GW with negative phase speeds and some part of GW with

FIG. A1. Seasonal cycle of E_{pV} at (a)–(c) ALOMAR and (d)–(f) Khlungsborn obtained from MERRA-2 at selected altitude ranges: 35–40 (green), 45–50 (black), and 55–60 km (red). Solid lines are obtained from 7 years (2012–18) of MERRA-2 data. Dashed lines show results for days of lidar observations. Each column shows the results for different methods used for calculation of E_{pV} : (left) unfiltered, (center) vertically filtered, and (right) temporally filtered. (a)–(f) Shaded regions show the standard deviations. (g)–(i) The ratio of E_{pV} between Khlungsborn and ALOMAR. The blue dashed line represents a ratio of 1. Note the different scales on the Y axis in (a) and (d) vs (b), (c), (e), and (f).

positive phase speeds are absorbed. We note that our lidar observations show a relatively small winter–summer variation for E_{pV} (typically a factor of ~ 1 –3) whereas SABER gives somewhat larger results (factor of ~ 3 –4).

Also emission of gravity waves by jets and fronts can be stronger pronounced in winter (e.g., Sato and Yoshiki 2008; Plougonven and Zhang 2014; de la Cmara and Lott 2015).

e. GW-scale height: Decrease of E_{pV} with altitude

Is the observed decrease of E_{pV} with altitude due to mean-flow impact or due to dissipation?

A part of the winter–summer difference is presumably related to the filtering mechanism discussed above: in winter GW with westward phase speeds can undisturbedly propagate from lower altitudes to the middle mesosphere, whereas they get absorbed in summer. Due to the increase of the wind with altitude (Fig. 16), the vertical wavelengths of GWs also increase with altitude [Eq. (4)]. This leads to more stable propagation conditions in winter compared to summer. But this also removes energy from our filtered data ($\lambda_z > 15$ km). Thus, H_{pV} of the vertically filtered data will be smaller than H_{pV} of the unfiltered data. This is exactly what we observe at lower altitudes over Khlungsborn (see Table 3).

Gravity waves respond to the ambient wind by changes in their wavenumber and amplitude. This leads to the expectation

that the E_{pV} will decrease with altitude in the stratosphere. Using the midfrequency approximation (that the intrinsic frequencies are well between the Coriolis and the Brunt–Visla frequency) one can deduce from the vertical invariance of the vertical wave-action flux that the E_{pV} should be proportional to the vertical wavenumber.

Thus, changes of E_{pV} relative to a reference altitude (z_{ref}), using Eq. (4) and neglecting the variation in N with height, can be written:

$$R = \frac{E_{pV}(z)}{E_{pV}(z_{\text{ref}})} = \frac{|v_{\phi,x} - \bar{u}|_{z_{\text{ref}}}}{|v_{\phi,x} - \bar{u}|_z}. \quad (7)$$

Note that here we assume that waves propagate in zonal direction. If this is not the case, the effect will be smaller and disappear if waves propagate perpendicular to the background wind. The changes of E_{pV} relative to the ground expected to be significant, but we used $z_{\text{ref}} = 30$ km, namely, the lowest height in our study. We varied $v_{\phi,x}$ from -20 to $+20$ m s $^{-1}$. Our results show that the variations of E_{pV} with altitude due to changes of the background winds are approximately in the range between $R = 0.5$ and $R = 2.0$. This is significantly smaller than the decline of E_{pV} with altitude as shown, for example, in Figs. 4 and 9. Thus, only a minor fraction of the observed decrease of

FIG. A2. As in Fig. A1, but for the seasonal cycle obtained from ERA5.

GWPED may be due to changes of E_{pV} even when conserving wave action.

f. Increase of E_{pV} above approximately 50 km in summer

Interestingly, E_{pV} is nearly constant or even increases with height in summer for altitudes above roughly 50–55 km (see Fig. 13). For lidar, this feature is very pronounced at ALOMAR (all filtering methods) and to a lesser extent also in Kühlungsborn. This behavior is also seen in the SABER profiles (Fig. 9). Comparison with Fig. 16 shows that the vertical gradient of mean zonal winds also changes from negative to positive around these altitudes. It is therefore tempting to assume that dissipation ends above roughly 50–55 km because filtering of GW stops at these altitudes since all GW with phase speeds larger (less negative) than the minimum wind have already been absorbed at lower heights and the rest (with even smaller phase speeds) can propagate freely further upward. Certainly, this is a crude description of much more complicated processes. It is therefore not surprising, that a detailed comparison of the summer E_{pV} and zonal wind profiles in Figs. 13 and 16 does not agree everywhere with this simple scenario.

7. Conclusions

In this paper we present a climatology of GW activity based on seven years of lidar observations at two locations in the

Northern Hemisphere, namely, at 54° and 69°N. We used high resolution measurements by two ground-based RMR lidars, satellite-borne SABER observations, as well as MERRA-2 and ERA5 data. For the sake of consistency, lidar and reanalysis data were analyzed in an identical manner. SABER data were analyzed to match the lidar/reanalysis procedure as close as possible. The altitude coverage of the measurements is 30 to 70 km. Considering sudden stratospheric warmings (SSW), we conclude that it is rather unlikely that SSW leads to a significant bias of our GWPED climatology in winter. Comparing SABER and reanalysis results from times with and without lidar observations, no significant difference is observed. We therefore conclude that the climatology derived from lidar observations is presumably representative regarding the variation of GWPED with season and altitude at both locations.

Absolute values of E_{pV} from SABER are very similar to vertically filtered lidar data ($\lambda_z < 15$ km) but are significantly larger than temporally filtered lidar data ($\tau < 8$ h), and smaller than unfiltered lidar data. Absolute values of E_{pV} from lidar and reanalyses are similar at both stations, but only at the lowest altitudes (in case of ERA5, up to 45 km and for MERRA-2 close to 30 km). In winter, E_{pV} from MERRA-2 and ERA5 are smaller by up to approximately two orders of magnitude (compared to lidar) where the difference increases with height. The situation is more complex in summer. The excessive decrease in GWPED in ERA5 can presumably be

FIG. B1. Average profiles of E_{pV} over ALOMAR during (left) Winter (December–February) and (right) summer (June–August). Blue solid lines show lidar measurements. SABER (black dashed lines), MERRA-2 (green dotted lines), and ERA5 (red dashed lines) are limited to profiles during days of lidar operation. Results are shown for (top) unfiltered, (center) vertically filtered, and (bottom) temporally filtered data. SABER data are the same in each row and irrespective of the filtering method of the other data.

FIG. B2. As in Fig. B1, but for Kühlungsborn location.

attributed to the sponge layers, whereas MERRA-2 shows overall lower values.

A pronounced seasonal cycle is observed for E_{pV} in most cases at both locations, namely, Kühlungsborn (54°N) and

ALOMAR (69°N). For example, lidars show maxima in winter and minima in summer at both locations for both the unfiltered and the vertically filtered data. The seasonal variation from SABER is similar but with a slightly larger winter–summer

TABLE C1. Seasonal variation of E_{pV} ($J m^{-3}$) for different altitude ranges (km) measured at ALOMAR.

variation. Regarding reanalysis data, MERRA-2 reproduces a winter maximum and summer minimum of similar magnitude compared to lidar, whereas the seasonal variation is much smaller in ERA5. The temporally filtered lidar measurements ($\tau < 8$ h) do not show any clear seasonal dependence. The winter–summer variation of E_{pV} is quantitatively rather different compared to the variation of E_{pm} . The latter is frequently used in the literature. We conclude that when comparing the seasonal variation of GWPED from different sources and at different locations one should carefully consider which quantity is actually discussed and if variations of the background atmosphere (density, buoyancy frequency, etc.) are carefully taken into account. A semiannual variation with a small amplitude is observed in the unfiltered data at Kühlungsborn and at ALOMAR. Such a semiannual modulation is also present in SABER and in reanalysis data.

Considering lidar measurements below 50 km, the decrease of E_{pV} with height is stronger in summer than in winter, irrespective of filtering method and location. The smallest decrease of E_{pV} with altitude (largest-scale heights H_{pV}) is observed in winter for lidar data with small periods (i.e., $\tau < 8$ h) at both stations. The conservation of wave action leads to a variation of E_{pV} with altitude which, however, is small compared to the observed variation of E_{pV} . For SABER, the energy-scale heights in winter and summer are roughly the same at both stations. At higher altitudes E_{pV} decreases rapidly with altitude in winter but it remains nearly constant in summer, consistent with the standard scenario of GW dissipation and filtering by background winds. In more detail, E_{pV} -scale

heights changes significantly with height and depend on, for example, filtering technique. This suggests that different parts of the GW spectrum dissipate at different altitudes, which also depends on season.

The value of E_{pV} at Kühlungsborn ($54^\circ N$) is significantly larger compared to that at ALOMAR ($69^\circ N$). This observation is opposite to simple scenarios, which take into account the potential impact of background winds on GW filtering and Doppler shifts of vertical wavelengths and periods. Part of the observed latitudinal difference can be explained by modulation of GW activity by the background winds. The analysis of saturation amplitudes shows that, for waves of slow ground based phase speed that are approaching instability, the wave amplitudes will be larger in regions where the winds are larger (cf. Ern et al. 2015). Comparing lidar with SABER, we note that the difference between both stations in lidar is presumably larger compared to similar stations at other longitudes. Sophisticated modeling involving more complicated processes such as horizontal propagation of GW over large distances, GW activity related to the position of the polar vortex, and secondary wave generation is required.

In summary, this study shows that information about GW from rather different sources (lidars, satellites, reanalyses) can provide details about the complex morphology of GW in terms of variation with altitude, latitude, and season as well as the contribution of different spectral components to the overall variability. In the end, the interplay between gravity wave sources, propagation, filtering and dissipation in an altitude and time dependent background atmosphere determines

TABLE C2. Seasonal variation of E_{pV} ($J m^{-3}$) for different altitude ranges (km) measured at Kühlungsborn.

FIG. D1. Time–height cross section of vertically filtered temperature fluctuations ($\text{GW } \lambda_z < 15 \text{ km}$) during (left) January and (right) August at ALOMAR from (top) ERA5 and (bottom) MERRA-2 data for the same dates as in Figs. 1 and 3.

the impact of gravity waves on the general circulation as well as related effects, e.g., transport of tracers.

Acknowledgments. This paper is a contribution to the project “Mesoscale energy cascades in the lower and middle atmosphere” of the Collaborative Research Centre TRR 181 “Energy Transfer in Atmosphere and Ocean” funded by the Deutsche Forschungsgemeinschaft (DFG; German Research Foundation)—Project TRR 181/T01. The work was also supported by the DFG Projects ER 474/4-2 (MS-GWaves/SV) and LU 1174/8-1 (MS-GWaves/PACOG) which are part of the DFG researchers group FOR 1898 (MS-GWaves). We are grateful to the team of the SABER instrument for providing and maintaining this excellent dataset.

Data availability statement. SABER data are publicly available at GATS Inc. at <http://saber.gats-inc.com>. Data in this paper are available at <ftp://ftp.iap-kborn.de/data-in-publications/StrelnikovaJAS2020/>.

APPENDIX A

Climatology from ERA5 and MERRA-2

Figures A1 and A2 show seasonal variations of E_{pV} for ALOMAR and Kühlungsborn in the three altitude ranges obtained from MERRA-2 and ERA-5, respectively.

APPENDIX B

Comparison of Obtained E_{pV} Profiles

A summary of all the obtained E_{pV} profiles is shown in this appendix. Figures B1 and in Fig. B2 show results for ALOMAR and Kühlungsborn, respectively. In these figures mean profiles of observed E_{pV} are shown separately for winter (DJF) and summer (JJA) months. SABER profiles in these figures are the same as shown in Fig. 9 by black solid lines. These profiles were obtained as described in section 3b and no additional filtering was applied. All other profiles were obtained as described in sections 1 and 2. Rows in every figure demonstrate the methods for temperature fluctuations estimation, i.e., unfiltered, vertically filtered or temporally filtered data. SABER, MERRA-2, and ERA5 data are limited to profiles during lidar operation. This, in particular, implies that if some special event (e.g., SSW) is missing in the lidar measurements, it does not appear also in the reanalyses data. And other way around, if such an event affects the lidar measurements, it must produce the same signature in the reanalysis data.

Profiles of the *unfiltered lidar* measurements above approximately 50 km both in summer and winter reveal higher values than all other results as shown in Figs. B1a, B1b, B2a, and B2b. Below $\sim 50 \text{ km}$ the unfiltered lidar observations show

better agreement with all other profiles in winter than in summer. SABER profiles demonstrate values relatively close to the lidar data only for Kühlungsborn location below ~ 35 km (Fig. B2a). All other SABER data show values which are considerably lower compared to lidar measurements. This is expected because of presence of tidal signatures in the unfiltered lidar data, but not in SABER results.

Figures B1c, B1d, B2c, and B2d demonstrate analysis results for the *vertically filtered* data. The best agreement between lidar and SABER observations and ERA5 results was found below ~ 45 km during summer months (Figs. B1d and B2d). Above this altitude a very strong decrease of E_{pV} in ERA5 data is obtained. In winter (Figs. B1c and B2c) lidar agrees well with SABER at ALOMAR between 40 and 55 km and with ERA5 at both locations only below 35 km. SABER data in winter often reveal slightly higher values than lidar measurements. This is most likely due to the presence of GW with vertical wavelength > 15 km in winter. Since the discrepancy between SABER and lidar results is larger at Kühlungsborn, we can assume, that contribution of GW with larger vertical wavelengths is stronger at this location. MERRA-2 results demonstrate very low values in all altitude ranges at both locations.

Results of *temporally filtered* data are summarized in Figs. B1e, B1f, B2e, and B2f. Good agreement with the lidar data was found for ERA5 in summer below 45 km. Above this height the decrease of E_{pV} with altitude is too strong in ERA5 results. At Kühlungsborn during wintertime (Fig. B2) the ERA5 data are lower than lidar measurements even below 45 km. Lower values of temporally filtered E_{pV} estimated from MERRA-2 data can be explained by poor temporal resolution. SABER E_{pV} values are higher than the temporally filtered lidar data because this type of the lidar data filtering removes the most energetic part of GW spectra.

APPENDIX C

Lidar Results of Seasonal Cycle of GWPED

Tables C1 and C2 summarize results of seasonal cycle of GWPED measured by lidar.

APPENDIX D

Example of Time–Height Cross Sections of Temperature Fluctuations from Reanalysis Data

Figure D1 shows an example of time–height cross sections of temperature fluctuations obtained from ERA-5 and MERRA-2 data.
