Annual Spring Experiments aim to accelerate the transfer of promising new concepts and tools from research to operations through intensive real-time forecasts and evaluations.

B **ACKGROUND.** Each spring during the climatological peak of the severe weather season in the United States, the Experimental Forecast Program (EFP) of the National Oceanic and Atmospheric Administration's (NOAA) Hazardous Weather Testbed (HWT) conducts a multiagency collaborative forecasting experiment known as the HWT EFP Spring Experiment. Organized by the Storm Prediction Center (SPC) and National Severe Storms Laboratory (NSSL), the annual Spring Experiments test new concepts and technologies designed to improve the prediction of hazardous mesoscale weather. A primary goal is to accelerate the transfer of promising new tools from research to operations, while inspiring new initiatives for operationally relevant research, through intensive real-time experimental forecasting and evaluation activities (e.g., Weiss et al. 2007). This article summarizes the activities and preliminary findings from the 2010 HWT EFP Spring Experiment (SE2010) conducted on 17 May–18 June.

The HWT is jointly managed by the SPC, NSSL, and the National Weather Service (NWS) Oklahoma City/Norman Weather Forecast Office (OUN), which are all located within the National Weather Center building on the University of Oklahoma's south research campus. HWT facilities include a combined forecast and research area situated between the SPC and OUN operations rooms (Fig. 1). The proximity to operational facilities, and access to data and workstations replicating those used operationally within the SPC, creates a unique environment supporting collaboration between researchers and operational forecasters on topics of mutual interest. The HWT organizational structure is composed of the EFP, whose specific mission is focused on predicting hazardous mesoscale weather events on time scales ranging from a few hours to a week in advance, and on spatial domains from several counties to the CONUS, as well as the Experimental Warning Program and Geostationary Operational Environmental Satellite-R (GOES-R) Proving Ground.

The 2010 NOAA/HWT Spring Forecasting Experiment (SE2010) was particularly noteworthy because, in addition to the traditional severe storms component, emphases were expanded to include heavy rainfall and aviation weather, through collaboration with the Hydrometeorological Prediction Center (HPC) and Aviation Weather Center (AWC), respectively. In addition, the Center for Analysis and Prediction of Storms (CAPS) at the University of Oklahoma provided unprecedented real-time continuous United States (CONUS) forecasts from a multimodel Storm-Scale Ensemble Forecast (SSEF) system with 26 members and 4-km grid spacing, as well as a single forecast with 1-km grid spacing. Several other organizations provided experimental model output, and the National Center for Atmospheric Research (NCAR)–NOAA Developmental Testbed Center (DTC) provided objective model evaluations.

The first official Spring Experiment occurred in 2000. Kain et al. (2003) detailed the pre-2003 experiments and the history of collaborative activities between NSSL scientists and local OUN forecasters. Additionally, Kain et al. (2003) articulated the ingredients necessary for a collaboration that is mutually beneficial to the participating operational and research organizations—namely, “Forecasters learn to address operational challenges from a more scientific perspective, while researchers become better equipped to pursue projects that have operational relevance” (p. 1798) (visit www.nssl.noaa.gov/projects/hwt/efp for information on past experiments).

Since 2003, Spring Experiments have examined experimental high-resolution “convection allowing” numerical weather prediction (NWP) models [hereafter convection-allowing models (CAMs)].

CAMs typically use grid spacing ≤ 4 km, which is about the coarsest grid spacing at which the evolution and dominant circulations within midlatitude mesoscale convective systems (MCSs) can be adequately represented (Weisman et al. 1997). Using 4-km grid spacing can be viewed as a resolution compromise—it is coarse enough so that current computers can generate forecasts quickly enough to provide operational guidance and fine enough to reasonably depict the phenomena of interest.

Successful real-time experiments using CAMs, such as those coordinated by CAPS in the mid-1990s (e.g., Xue et al. 1996; Droegemeier et al. 1996) using the Advanced Regional Prediction System (ARPS; Xue et al. 2003) and by NCAR in 2003 using the Weather Research and Forecasting (WRF) model (Skamarock et al. 2008) in support of the Bow Echo and Mesoscale Convective Vortex (MCV) Experiment (BAMEX; Davis et al. 2004), paved the way for recent experiments using CAMs. From these earlier experiments, it became clear that CAMs could depict realistic MCSs—at times with surprising accuracy—and improve forecasts of MCS frequency and convective mode relative to coarser simulations using cumulus parameterization (Done et al. 2004). Since the initial explorations during 2003/04 (Kain et al. 2006), testing and evaluating of CAM systems has become a recurring theme of subsequent Spring Experiments with NCAR, the Environmental Modeling Center (EMC), and CAPS providing unique convection-allowing WRF model guidance each year. Furthermore, for many SPC forecasters, involvement in Spring Experiments and the demonstrable value of CAM products have led to the integration of these products into their suite of routine forecast guidance. CAMs add value because they *explicitly* simulate the

convective mode, providing valuable information on potential hazards,¹ in contrast to coarser convection-parameterizing models, from which convective hazards are mostly inferred through aspects of the forecast synoptic and mesoscale environment.

It is well known that to achieve maximum value and account for forecast uncertainty—which can be large even at very short lead times because of the nonlinear error growth associated with convective processes—a properly calibrated ensemble is needed (Fritsch and Carbone 2004; Eckel et al. 2009). The challenges for developing CAM ensembles include increased computational requirements, along with developing appropriate ensemble perturbation, calibration, and visualization methods. We believe that these challenges are formidable, but that the motivation for developing CAM ensembles is strong. Aspects of CAM forecasts that are improved relative to convection-parameterizing forecasts, such as statistical properties of convective rainfall (e.g., Davis et al. 2004) and the depiction of the diurnal precipitation cycle (Clark et al. 2007, 2009; Weisman et al. 2008), strongly suggest that CAM ensemble forecasts would be more representative of possible future atmospheric states than coarser convection-parameterizing ensembles [e.g., the National Centers for Environmental Prediction's (NCEP) Short-Range Ensemble Forecast (SREF) system (Du et al. 2006)].

To begin addressing the challenges of CAM ensembles, CAPS developed the first real-time, large-domain SSEF system in collaboration with the HWT for the 2007 Spring Experiment through multiyear support provided by the NOAA Collaborative

Science, Technology, and Applied Research (CSTAR) program (Xue et al. 2007; Kong et al. 2007). Each year since 2007, improvements have been made to the SSEF system based on experience from previous years, advances in numerical modeling, and improvements in computing capabilities. Details on past SSEF systems can be found in Xue et al. (2007, 2008, 2009, 2010), Kong et al. (2007, 2008, 2009), and Levit et al. (2010). Despite SE2010 providing a very effective platform for testing SSEF systems, the very large volume of data and the comparatively limited time for model interrogation requires that rigorous examination of key science issues be addressed in postexperiment analysis. Thus, CAPS has archived all the raw model output from which several formal articles have already been produced (e.g., Clark et al. 2009, 2010b,c, 2011; Kain et al. 2010b,a; Schwartz et al. 2010; Coniglio et al. 2010).

The advent of the SSEF system marks a new and exciting phase of the HWT EFP Spring Experiment, and recent activities match very well the longer-term goals of NOAA. These goals include developing a robust mesoscale probabilistic NWP capability that fits within the “4D datacube” planned for the Next Generation Air Transportation System (NextGen) by 2016 (Eckel et al. 2009) as well as the Warn-on-Forecast concept (Stensrud et al. 2009). In fact, the success of the Spring Experiment in facilitating testing of innovative products and methods designed to improve NWS forecasting has led to collaborative involvement from the NWS Office of Science and Technology (NWS OST) in planning future experiments.

¹ Although tornadoes, high winds, and large hail cannot be resolved at 4-km grid spacing, these hazards are closely related to convective mode and morphology (Gallus et al. 2008; Duda and Gallus 2010; Smith et al. 2010), which CAMs are demonstrably capable of simulating (e.g., Done et al. 2004; Weisman et al. 2008).

SE2010 PARTICIPANTS AND PRIMARY COMPONENT OBJECTIVES.

More than 70 operational forecasters, research scientists, academic faculty, graduate students, and administrators from organizations across the United States participated in SE2010. Visitors generally participated for week-long periods, with several SPC and NSSL forecasters and scientists present throughout the experiment guiding daily activities and providing weekly training and continuity. The Spring Experiment Operations Plan (http://hwt.nssl.noaa.gov/Spring_2010/Spring_Experiment_2010_ops_plan_21May.pdf) lists all the participants, and Table 1 lists the participating agencies.

SE2010 activities occurred weekdays (7:30 a.m.–4:00 p.m.) for five weeks (17 May–18 June) within three separate components at adjacent workstations in the HWT. Previously, the severe weather component

led by the SPC/NSSL was the sole focus. SE2010 activities were expanded to include aviation weather and quantitative precipitation forecasting (QPF) components led by the AWC and HPC, respectively. Most participants rotated to different groups each day. QPF activities were limited to the morning, so that QPF participants moved to the severe or aviation weather component during the afternoon.

The addition of QPF and aviation components was motivated by promising results from previous years in utilizing CAMs for severe weather forecasting and their seemingly natural extension to QPF and aviation weather—applications where the range of societal impacts extends beyond that of severe storms. For example, NOAA statistics indicate warm-season thunderstorms cause ~70% of U.S. air traffic delays and cost the economy more than \$4 billion (U.S. dollars) annually (see www.economics.noaa.gov/),

and flash floods are a leading cause of weather-related fatalities. SE2010 also marked the third year of collaboration with DTC researchers, who provided near-real-time objective evaluations of the experimental forecasts to supplement daily subjective model assessments; for detailed descriptions of DTC's Spring Experiment activities see Jensen et al. (2010a,b).

Daily forecasting and evaluation activities for each component occurred at similar times, providing common discussion periods to share insights on each group's respective forecast challenges. This schedule also indirectly allowed the exploration of forecast consistency between the three components. The primary objectives for each component were based on mission-specific needs and each NCEP center's previous experience with CAMs. SPC forecasters

have used CAM output since 2004, whereas most HPC and AWC forecasters have only limited experience with CAMs. Overall, the primary objectives for each component were similarly designed to i) allow forecasters to explore the potential operational uses of the CAM systems, ii) test experimental probabilistic forecast products, and iii) provide feedback to model developers on the strengths and weaknesses of the current systems. The basic objectives and experimental forecast products (examples in Fig. 2) for each component are listed below.

Severe convective storms component. PRIMARY OBJECTIVES. The objectives were to continue testing and evaluating the CAM systems in providing useful guidance for generating probabilistic severe weather outlooks with

d) Severe Component Discussion for 24 May 2010

THE HI-RES GUIDANCE INDICATED TWO CORRIDORS OF SEVERE WEATHER POTENTIAL...ONE ALONG THE EASTWARD SURGING COLD FRONT OVER THE CENTRAL HIGH PLAINS, AND THE SECOND ALONG THE WARM FRONT AND IN THE VICINITY OF THE LIFTING SURFACE LOW OVER THE NORTHERN PLAINS. THE STORMS ALIGN FAIRLY WELL WITH THE OBSERVED PLACEMENT OF SURFACE FEATURES. A SECOND AREA OF STORMS ALSO DEVELOPS IN HI-RES GUIDANCE OVER EASTERN SD/NEB. WE ARE UNCERTAIN WHETHER THESE STORMS WILL BE REAL FEATURES IN THE ATMOSPHERE GIVEN A LACK OF LOW-LEVEL FORCING. THOUGH AN UPPER DISTURBANCE OBSERVED IN WV IMAGERY WILL APPROACH THAT REGION AND COULD PROVIDE A FAVORABLE ZONE OF ASCENT FOR STORM INITIATION. REFLECTIVITY STRUCTURES NEAR AND EAST OF THE LIFTING SURFACE LOW OVER SD/NEB SHOW POSSIBLE SUPERCELL STORM TYPES, WHICH IS CONFIRMED IN HOURLY MAX UPDRAFT HELICITY. THESE STRUCTURES ARE IN LINE WITH FAVORABLE SHEAR/INSTABILITY PARAMETERS INDICATED IN 40KM OPERATIONAL NAM AND CURRENT SURFACE OA DATA. VERTICALLY INTEGRATED GRAUPEL FROM HI-RES GUIDANCE IS LARGE IN MAGNITUDE AND WIDESPREAD ACROSS THE FORECAST AREA DOMAIN, AND WIND SIGNATURES ARE DEPICTED AS WELL. THE LARGE VALUES OF UD-HELICITY ALONG WITH HAIL/WIND SIGNATURES INDICATE THAT A FEW HIGHER-END STORMS MAY BE POSSIBLE (WHICH WE ALSO DETERMINED BASED ON OBSERVED FEATURES AS WELL AS OPERATIONAL MODEL GUIDANCE)...WHICH GIVES US CONFIDENCE IN FORECASTING A SIG-SVR HATCHED AREA. OVERALL, WIDESPREAD CONVECTION IS FORECAST BY HI-RES GUIDANCE, WHICH WE BELIEVE IS LIKELY GIVEN THE STRONG FORCING ASSOCIATED WITH THE APPROACHING UPPER TROUGH OVERSPREADING A LARGE AREA OF HIGH INSTABILITY/MOISTURE.

FIG. 2. (a) A preliminary (i.e., issued in the morning) severe weather outlook valid for the 4-h period 2000 UTC 24 May–0000 UTC 25 May 2010. Contours for 5% (brown), 15% (yellow), 30% (red), and 45% (purple) probabilities of severe weather (i.e., tornadoes, hail size ≥ 1 in., and wind gusts ≥ 50 kt) within 25 mi of a point are shown. Hatching marks areas with 10% or greater probability of significant severe weather (i.e., EF2 or greater tornadoes, hail size ≥ 2 in., and wind gusts ≥ 65 kt) within 25 mi of a point. Locations of observed severe weather during the outlook period are marked (see legend in top left). (b) A QPF outlook for 6-h accumulated precipitation greater than 0.5 in. for the period ending 0000 UTC 15 Jun 2010. Contours for 25% (slight; white), 50% (moderate; yellow), and 75% (high; purple) probabilities are shown. Areas where observed precipitation was greater than 0.5 in. during the outlook period are shaded (first shading level is for 0.5 in.). (c) Preliminary aviation outlook for instantaneous reflectivity greater than 40 dBZ valid 2100 UTC 24 May 2010. Contours for 25% (slight; green) and 50% (moderate; red) are shown. Areas where observed reflectivity was greater than 40 dBZ at the valid time are shaded. (d) Accompanying severe component discussion.

a focus on improving forecasts of initiation, evolution, mode, and intensity of convective storms.

EXPERIMENTAL FORECAST PRODUCTS. Outlooks were issued over movable domains approximately 8° latitude $\times$ 14° longitude. The placement of the daily domain was determined based on where severe convective impacts or forecast challenges were expected to be greatest, in consultation with SPC forecasters working the operational day shift.

The outlooks generated were similar to SPC's operational day 1 convective outlooks but with higher temporal resolution to complement the current experimental day 1 enhanced-resolution probabilistic thunderstorm product (www.spc.noaa.gov/products/exper/enhtstm/). The graphical outlooks consisted of probabilistic forecasts for any severe convective weather (i.e., hail diameter ≥ 1 in., wind gusts ≥ 50 kt, and tornadoes) within 25 mi of a point during the 2000–0000 and 0000–0400 UTC periods. Following SPC conventions, probability contours were drawn at 5%, 15%, 30%, 45%, and 60%. In addition, hatched shading was used to delineate regions where a 10% or greater probability existed for significant severe events (i.e., EF2 or greater tornado, hail diameter ≥ 2 in., and/or wind gusts ≥ 65 kt). A text discussion (e.g., Fig. 2d) was also included, providing forecast reasoning with an emphasis on CAM guidance utility. The experimental preliminary outlooks were issued daily by 1530 UTC and then updated by 1930 UTC. A team-generated outlook issued 24 May 2010 is shown in Fig. 2a.

Aviation weather component. PRIMARY OBJECTIVES. The objectives were to explore the potential of the CAM system to provide useful guidance for probabilistic thunderstorm forecasts, emphasizing timing, location, coverage (porosity), and thunderstorm tops—critical areas for efficient management of the National Airspace System.

EXPERIMENTAL FORECAST PRODUCTS. The human-generated outlooks covered a fixed domain over the high air-traffic regions of the central and eastern United States. The graphical outlooks consisted of probabilistic thunderstorm (defined as reflectivity ≥ 40 dBZ) forecasts for three “snapshot” times valid at 2100, 2300, and 0100 UTC (Fig. 2c). Probability contours

were drawn for 25%, 50%, and 75%, corresponding to the descriptors slight, moderate, and high, respectively, which represented the coverage of thunderstorms. Predictions of broken or solid lines of storms were indicated by dashed lines on the snapshot graphic. A separate product was produced for the probability of thunderstorm tops $\geq 25,000$ ft² using the same slight (25%), moderate (50%), and high (75%) probability contours. The aviation products were designed to complement AWC's operational Collaborative Convective Forecast Product (<http://aviationweather.gov/products/ccfp/>). As in the severe weather component, products were issued by 1530 UTC and updated by 1930 UTC, and included text providing forecast reasoning and CAM utility. During the afternoon, the aviation team split into one group focused on the aforementioned day 1 products and another group that generated a day 2 probabilistic thunderstorm forecast valid 1800–0000 UTC the following day for experimental aviation strategic planning purposes. Again, the 40-dBZ reflectivity threshold defined thunderstorms, and the same probability contours corresponding to slight, moderate, and high were used for the outlooks.

QPF component. PRIMARY OBJECTIVES. The objectives were to explore the utility of the CAM systems in providing guidance for experimental probabilistic 6-h QPF products.

EXPERIMENTAL FORECAST PRODUCTS. Team-generated QPF products included the probability of 6-h rainfall exceeding 0.50 and 1.00 in. for the periods 1800–0000 and 0000–0600 UTC. These products with text discussions were issued daily by 1530 UTC over the same movable domain as the severe weather component. The experimental probabilistic QPF graphics used the categorical terms slight, moderate, and high to denote forecast probabilities of 25%, 50%, and 75%, respectively, and were a large departure from the standard deterministic QPF products issued operationally at the HPC. A prediction for the maximum 6-h rainfall amount within the highest probability contour for 1.00-in. exceedance was also included in the graphic.³ Afternoon updates were not issued for QPF products. An example outlook is shown in Fig. 2b.

EXPERIMENTAL MODEL GUIDANCE AND PRODUCTS. SE2010 benefitted from ex-

² The thunderstorm top threshold was changed to $\geq 35,000$ ft midway through SE2010 based on recommendations by FAA participants.

³ If probabilities were below slight (25%) for the entire domain, a maximum amount was not indicated.

perimental CAM guidance contributed by CAPS, EMC, the NOAA Earth Systems Research Laboratory Global Systems Division (NOAA/ESRL/GSD), NSSL, and NCAR. Each of these collaborators provided 0000 UTC initialized model guidance, and most provided guidance from additional model runs initialized at 1200 UTC and/or other times. The computational domains covered from three-fourths to full CONUS regions, and most 0000 UTC initialized models produced forecasts for at least 30-h lead times. The cornerstone of the SE2010 experimental model guidance was a 4-km grid spacing, 26-member multimodel SSEF system produced by CAPS. CAPS also produced a 30-h CONUS domain simulation with 1-km grid spacing. Details on model guidance contributed by each organization are provided in the online supplement (<http://dx.doi.org/10.1175/BAMS-D-11-00040.2>).

CAM-derived products based on explicitly simulated storm characteristics were emphasized during the generation of outlooks for all three components. Some of these products (e.g., simulated reflectivity) have been used in previous Spring Experiments, while others were newly developed specifically for aviation and QPF components. Given the finescale, high-amplitude, and discontinuous nature of the simulated storm fields, generating useful SSEF ensemble-mean fields is quite challenging. For example, consider ensemble forecasts containing individual realizations of slightly displaced convective systems. Clearly, an ensemble-mean based on averaging all members would smooth out the high-amplitude features and sharp gradients, obfuscating relevant information such as system mode and intensity. To retain the amplitude of the simulated model features, a technique called “probability matching” (Ebert 2001; Clark et al. 2009) was utilized as an alternative to the traditional ensemble mean for fields such as precipitation and simulated reflectivity. Probability matching basically involves replacing the ensemble-mean distribution with a distribution sampled from the individual ensemble members and thus helps retain the amplitude of individual members.

Further challenges in generating useful probabilistic products are caused by the inherent low probability of severe weather on the 4-km grid scale. For example, even during widespread severe weather outbreaks, the probability that a particular grid box will experience severe weather is very low. These low-probability events can be viewed as occurring at the tail of the forecast probability distribution function (PDF), where it would take an ensemble with much larger membership than the SSEF system to generate reliable forecast

probabilities (e.g., Richardson 2001). One way to provide more useful probabilistic information from a limited-size ensemble is to consider the probabilities of severe weather occurring within a specified radius of each model grid point. This way, a larger area is considered over which it is inherently more likely that severe weather will occur, and the forecast event moves away from the tail of the forecast PDF, where fewer members are required to generate reliable forecasts. Following this idea, for selected SSEF system fields, neighborhood probabilities were computed for the probability of events occurring within a 40-km radius of each grid point (this is consistent with operational SPC probabilistic severe weather outlooks). To eliminate some of the sharp circular edges in the probability fields that result from using circular areas and to account for additional spatial uncertainty, a 2D Gaussian smoother (e.g., Brooks et al. 1998) was applied to the neighborhood probabilities (weighting function, $\sigma = 10$ grid points). Methods for generating useful probabilistic information from CAM systems are still being researched (e.g., Sobash et al. 2011; Marsh et al. 2012).

A list of CAM-derived products can be found in the CAPS Spring Experiment Program plan (http://forecast.caps.ou.edu/SpringProgram2010_Plan_Brief.pdf). Generally, the fields available from the SSEF members were also available from the deterministic CAMs used in SE2010. The following sections highlight some of the more widely used and innovative products, along with some of the methods used by DTC for objective evaluation.

Simulated reflectivity. Computing and then adding “equivalent reflectivity factors” (e.g., Xue et al. 2003; Koch et al. 2005) for each simulated hydrometeor species yields model-simulated reflectivity (after converting units to dBZ), which is a very useful product for monitoring the characteristics of CAM storms and was heavily utilized during SE2010. Along with displays of simulated reflectivity from a single model, “spaghetti plots” of reflectivity exceeding a specified threshold from the SSEF members were often displayed, and SSEF-derived ensemble mean, probability matched, and neighborhood probability reflectivity products were also often utilized. Figure 3 shows the simulated reflectivity from four SSEF members with only varied microphysics parameterizations (Figs. 3a–d) and the CAPS run with 1-km grid spacing (Fig. 3e) with corresponding observations (Fig. 3f) for 27-h forecasts initialized 0000 UTC 18 June.

Model-simulated satellite imagery. Working with scientists at both the Cooperative Institute for Research in

the Atmosphere (CIRA) at Colorado State University (CSU) and the Cooperative Institute for Meteorological Satellite Studies (CIMSS) at the University of Wisconsin (UW), simulated (or synthetic) satellite imagery (e.g., Grasso et al. 2008; Otkin and Greenwald 2008) was produced for SE2010. CIRA and CIMSS generated this imagery by running local versions of radiative transfer models with moisture, temperature, and hydrometeor fields in the NSSL WRF model to create simulated radiance/brightness temperature fields. Animations of simulated satellite imagery can allow forecasters to rapidly discern simulated dynamic processes, such as moisture transport, ascent

FIG. 5. HMF updraft helicity ($\text{m}^2 \text{s}^{-2}$) from 25-h forecasts initialized 0000 UTC 10 May 2010 from (a) the ARW control member of the SSEF system and (b) the CAPS run with 1-km grid spacing. (c) Maximum HMF updraft helicity from any SSEF member. (d) Neighborhood probabilities for updraft helicity greater than $100 \text{ m}^2 \text{s}^{-2}$, and storm reports that occurred between 0000 and 0100 UTC 11 May (legend in top right).

and subsidence, and shallow and deep convection, improving our understanding of model forecast evolution. Examples of simulated satellite imagery produced by CIRA and CIMSS are shown in Fig. 4. Real-time forecast imagery is available year-round in SPC workstations and online (at www.nssl.noaa.gov/wrf/).

HMFs. Hourly output of “traditional” fields (e.g., mean sea level pressure, geopotential height, 700-hPa temperatures) was available from SE2010 CAM guidance. However, smaller-scale features, such as those in explicitly simulated storms, often evolve on time scales of minutes rather than hours. To monitor the behavior of such features, Kain et al. (2010b) developed a strategy to track small-scale, rapidly changing features at every model time step between regular hourly model output times. Individual gridpoint temporal maximum values from each hour are stored in two-dimensional fields that are saved at the regular hourly output intervals. These hourly maximum fields (HMFs) provide useful

information on peak intensity and track of simulated storm features without storing every time step of all the model fields.

In the SSEF system, HMFs were computed for six diagnostic fields conceptually thought to be related to CAM storm attributes and potential severe convective hazards: i) maximum updraft and ii) maximum downdraft velocities between 3- and 6-km AGL, which indicate the intensity of convective overturning; iii) simulated reflectivity at 1-km AGL, which should also be related to the intensity of convection; iv) updraft helicity (Kain et al. 2008)—the integral of vertical vorticity times updraft velocity between 2- and 5-km AGL—which is designed to detect mesocyclones in model-simulated storms; v) wind speeds at 10-m AGL, which was tested for predicting severe surface wind gusts; and vi) vertically integrated graupel (or depth of equivalent liquid in m), which was tested for predicting large hail. To complement HMF displays from single-model forecasts, maximum values of HMFs from any SSEF member were displayed, which

Corresponding observed objects in (h)–(l) are indicated by blue contours.

supercells that tracked across Oklahoma and Kansas, producing damaging tornadoes, wind, and hail.

QPF products. To facilitate the QPF component, several SSEF-derived precipitation products were developed. Additionally, for comparison to operational guidance, corresponding products were made available from NCEP’s SREF system. These products included the traditional ensemble mean, the probability matched ensemble mean, and the maximum from any member of 6-h accumulated precipitation. Traditional (or gridpoint based) forecast probabilities, as well as neighborhood probabilities, of precipitation greater than 0.5, 1.0, and 2.0 in. were provided. Forecasts from deterministic CAMs were also compared to products from the operational North American Mesoscale (NAM) Model. For verification, NSSL’s National Mosaic and Multi-Sensor Quantitative Precipitation Estimation (QPE) (NMQ; Zhang et al. 2011) dataset was used. Illustrating these products, forecasts of an MCS-related heavy rainfall event in Iowa are shown in Fig. 6.

Aviation products. Several SSEF-derived products were developed to support the aviation component. One such product is “linear-mode probability,” which

indicates the probability of a contiguous line of storms. Porosity of convective systems (i.e., the amount of space between individual storms) is very important for aviation because planes can often navigate through spaces in noncontiguous regions of convection, but they generally have to navigate around contiguous lines. The linear-mode algorithm identifies areas where simulated reflectivity exceeds 35 dBZ and then estimates the mean length-to-width ratio of the contiguous area, searching for ratios greater than 5:1. Grid points are “flagged” for lengths exceeding 50, 100, and 200 mi; probabilities are computed based on the number of flagged ensemble members within 25 mi of each grid point. Another important property of convection for aviation is thunderstorm height. For SE2010, model-simulated storm heights were computed by finding the maximum height of 18-dBZ reflectivity. Then, SSEF-derived neighborhood probabilities for storm tops exceeding 25,000, 35,000, and 50,000 ft were computed. For verification, NSSL’s NMQ dataset includes a high-resolution 3D reflectivity grid from which storm top heights can be estimated. Example aviation products are shown in Fig. 7.

DTC objective evaluation products. The DTC provided objective verification of several deterministic and

probabilistic fields from experimental and operational models using Meteorological Evaluation Tools (MET; Developmental Testbed Center 2010). Again, NSSL's NMQ provided the verification dataset. Emphasis was placed on the object-based verification tool available in the MET package called Method for Object-based Diagnostic Evaluation (MODE; Davis et al. 2006), although traditional metrics (e.g., Gilbert skill score and bias) were also computed. Graphs and spatial plots illustrating output from the MET package were available through an interactive Web site under development by DTC (<http://verif.rap.ucar.edu/eval/hwt/2010/>) (e.g., Fig. 8).

RESULTS FROM MODEL EVALUATIONS.

Web-based forms were used to document aspects of experimental model forecasts relevant to each component. A large set of different model aspects were assessed. This section only examines a few aspects for which survey answers were mostly complete and contained interesting and meaningful results, which are summarized in Table 2. These subjective results are preliminary. More detailed work on each aspect is forthcoming. Please note

that all of the quotations in this section can be found in an archive maintained by the SPC at www.surveymonkey.com.

Evaluation of SSEF microphysics perturbations. Severe weather groups compared forecasts from four SSEF members identically configured except for the microphysics parameterization. The microphysics schemes were Thompson et al. (2004), WRF single-moment 6-class (WSM-6; Hong and Lim 2006), WRF double-moment 6-class (WDM6; Lim and Hong 2010), and Morrison et al. (2005). Specifically, survey participants were asked to “Comment on any differences and perceived level of skill in forecasts of composite reflectivity between control member CN (Thompson), m15 (WDM6), m16 (WSM6), and m17 (Morrison), over the evaluation domain and during the 20z-04z period . . .” Microphysics sensitivities were of particular interest during SE2010 because two “double moment” schemes—WDM6 and Morrison—were newly available in WRF version 3.1.1 and were used for the SSEF system. Double-moment schemes, which contain prognostic equations for both mixing ratios and number concentrations of

TABLE 2. Percentage of responses to selected survey questions (frequencies in parentheses).

Q1) Percentage of responses (%) to whether the perceived skill of the 1200 UTC forecasts was better than the 0000 UTC forecasts in the WRF NMM simulation contributed by EMC and the ARW-WRF simulation contributed by NCAR.						
	Yes, it is better	It is about the same	No, it is worse	N/A		
WRF NMM (EMC)	47.4 (9)	15.8 (3)	31.6 (6)	5.3 (1)		
ARW WRF (NCAR)	36.8 (7)	31.6 (6)	5.3 (1)	26.3 (5)		
Q2) Percentage of responses (%) to whether the perceived skill of the CAPS forecast with 1-km grid spacing was better than the forecast with 4-km grid spacing for mesoscale evolution of convection.						
	1 km better than 4 km	1 km similar to 4 km	1 km worse than 4 km	N/A		
	20.8 (5)	54.2 (13)	16.7 (4)	8.3 (2)		
Q3) Percentage of responses (%) to the perceived level of skill in SSEF 6-h precipitation forecasts relative to SREF forecasts for the periods 1800–0000 and 0000–0600 UTC.						
	Much better	Better	About the same	Worse	Much worse	N/A
1800–0000 UTC	34.8 (8)	34.8 (8)	17.4 (4)	4.3 (1)	4.3 (1)	4.3 (1)
0000–0600 UTC	28.6 (6)	28.6 (6)	33.3 (7)	4.8 (1)	0 (0)	4.8 (1)
Q4) Percentage of responses (%) to whether the perceived level of skill in the subsequent HRRR initializations is better, worse, or about the same relative to earlier initializations.						
	Yes, it is better	It is about the same	No, it is worse	N/A		
	44.8 (8)	44.8 (8)	5.6 (1)	5.6 (1)		

certain hydrometeor species, are more sophisticated and computationally expensive than single-moment schemes that contain prognostic equations only for hydrometeor mixing ratios.

Survey respondents often noted large differences in the simulations with different microphysics, but no single scheme seemed to outperform the others during SE2010. On many days, the Thompson run was the outlier among the four members, generating much more extensive regions of stratiform reflectivity. Furthermore, the Thompson member was most often noted for spurious convection. However, for organized MCSs that occurred near the end of the forecast period, Thompson often had superior placement, which was thought to be related to differences in simulated cold pool strength. Examination of 2-m temperatures (not shown) revealed a tendency for the non-Thompson schemes to generate stronger (i.e., colder) cold pools and associated MCSs that propagated too quickly toward the east and/or south. The Thompson forecasts had weaker cold pools that appeared more realistic and were associated with smaller MCS displacement errors.

Further evidence for these location differences was obtained objectively using a simple compositing method introduced by Clark et al. (2010a) and illustrated in Fig. 9. This technique searches within a 250-km radius of each grid point with a forecast event—in this case, 1-h rainfall ≥ 0.50 in.—and finds the conditional distribution of observed events. Composite distributions of observed events are then obtained by summing over all the cases [see Clark et al. (2010a) for further details]. At forecast hour 30, the Thompson forecasts show minimal system-

atic displacement error, while the non-Thompson schemes are associated with southward and eastward displacement errors. Similar differences in displacement errors and the tendency for the Thompson scheme to generate more extensive stratiform regions of reflectivity can be seen comparing the mixed microphysics members in Fig. 3.

Comparison of 0000 and 1200 UTC WRF forecasts from EMC and NCAR. Experimental guidance from models initialized at 0000 UTC was used to generate preliminary severe weather outlooks each morning, with 1200 UTC initialized guidance becoming available in time for the afternoon outlook updates. The deadline for the issuance of updates was 30 min before the 2000–0400 UTC forecast period began. For such short-term forecasts, SPC forecasters heavily rely on observational data for diagnostic assessments. However, as the update frequency of CAMs increases, it is hoped that guidance from such models can also provide short-term forecast value by improving upon earlier model initializations. With these issues in mind, this evaluation asked the severe weather team to rate the perceived skill of separate 1200 UTC initialized CAMs produced by EMC and NCAR relative to their 0000 UTC counterparts.

For both EMC and NCAR simulations, the 1200 UTC runs were most frequently rated as either “about the same” or “superior” to the 0000 UTC runs (Q1 in Table 2). However, there were a surprisingly large number of cases in which the 1200 UTC EMC runs were rated “worse” than the corresponding 0000 UTC runs. For these worse cases, it is believed

FIG. 9. Composite frequencies of observed rainfall greater than 0.50 in. relative to grid points forecasting rainfall greater than 0.50 in. at forecast hour 30 from SSEF members using (a) Thompson, (b) WSM6, (c) WDM6, and (d) Morrison microphysics parameterizations. Boldface dot in each panel marks the center of the composite domain.

that the poor depiction of nocturnal convection present at initialization contributed to erroneous forecasts, which was reflected in the following sample comment:

The 1200 UTC WRF-NMM [nonhydrostatic mesoscale model] very poorly initialized ongoing convection in AR and TX resulting in misplaced boundaries and very unrealistic convective evolution. Closer inspection of the initialized fields revealed that the outflow boundaries in the ICs [initial conditions] were too smooth and after only an hour or two into the simulation the model just got rid of the outflow boundaries.

These results are generally consistent with Weiss et al. (2010). Note, the EMC runs were “cold start” initializations using ICs from a 32-km grid of the operational NAM, which may be too coarse to resolve smaller-scale boundaries. The NCAR runs used higher-resolution 13-km Rapid Update Cycle (RUC) ICs, which incorporate a more sophisticated initialization procedure utilizing radar data. Thus, the smaller number of worse cases in the NCAR relative to the EMC runs may have been related to the different ICs. As previously mentioned, details on model configurations are provided in the supplementary material.

Comparison of simulated reflectivity in CAPS Advanced Research WRF model (ARW-WRF) forecasts with 1- and 4-km grid spacing. Previous work in similar convective regimes indicates that decreasing horizontal grid spacing from 4- to 2 km provides more detailed structure, but little added value, for next-day guidance of severe convection and heavy rainfall (Kain et al. 2008; Schwartz et al. 2009). To explore whether further reductions in grid spacing are needed to begin seeing added value relative to the 4-km forecasts, CAPS began producing forecasts with 1-km grid spacing for Spring Experiments in 2009 and 2010. Thus, this evaluation assessed the additional value (if any) in the mesoscale evolution of convection by reducing grid spacing from 4 to 1 km. Considering the 1-km AGL simulated reflectivity compared to corresponding observations and focusing on the 2000–0400 UTC period for mesoscale aspects of convection, such as mode, movement, and initiation, the severe weather team rated the 1-km forecast as “better,” “similar,” or “worse” than the 4-km forecast.

The results (Q2 in Table 2) imply little added value using 1-km grid spacing for the given forecast period. Although there were five instances in which the 1-km

run was rated better than the 4-km run, there were four cases in which the 1-km run was rated worse. By far, the 1- and 4-km runs were most frequently rated similar (13 instances). In the archived comments, participants often noted finer-scale details present in the 1-km runs that would not have added value to the types of severe weather forecasts made in SE2010. For example, comments included the following:

On 18 May: “If we look hard, there are subtle differences that can be noted between 4 and 1-km. However, the forecasts were generally very similar with respect to evolution, placement, time . . . etc.”

On 26 May: “Both under-predict the dry-line convection along TX/NM and they both correctly predict the KS MCS. Upon close examination of the forecasts, there are many differences in some of the storm scale details, but these smaller scale details didn’t really result in differences in skill.”

On 9 June: “There were some noticeable smaller scale differences between the 1 and 4-km, but they looked more like each other than they did the observations.”

The 10 May 2010 tornado outbreak in Oklahoma was an interesting case for comparing the 4- and 1-km runs. Comparing hourly max updraft helicity (UH) (Figs. 5a,b) clearly shows that the 1-km run developed multiple storms with strong rotation (maximum UH values were greater than $1,000 \text{ m}^2 \text{ s}^{-2}$) in northeast Oklahoma/southeast Kansas, while the 4-km run only developed one weakly rotating storm in southeast Kansas. Although the 1-km simulated storms were displaced north and east relative to observed ones, the number and intensity of storms predicted by the 1-km run was more consistent with observations than the 4-km run on this day. Clearly, the sensitivity to horizontal resolution is a complicated issue that deserves further attention.

Evaluation of SREF and SSEF precipitation forecasts. Recent studies (e.g., Clark et al. 2009, 2010a) using objective metrics generally indicate significant added value for convection-allowing relative to convection-parameterizing precipitation forecasts, especially for precipitation associated with organized convection. However, prior to SE2010, CAM QPF guidance had not been systematically evaluated in a pseudo-operational environment. Thus, SE2010 provided an ideal setting to gauge the potential usefulness of SSEF precipitation products, especially

in comparison to SREF products. For example, in one survey form QPF component participants were asked, To what degree did the SSEF 6-h precipitation forecasts provide added value over the SREF 6-h precipitation forecasts?

The subjective ratings (Q3 in Table 2) strongly indicated SSEF provided added value over SREF. For the 1800–0000 UTC period, 16 of 22 responses rated SSEF as “much better” or “better” than SREF, with only two instances in which SSEF was rated “worse” or “much worse” than SREF (four ratings were “about the same”). For the 0000–0600 UTC period, a larger portion of the responses rated SSEF and SREF “about the same” (7 of 20), but a majority (12 of 20) rated SSEF as “better” or “much better” than SREF, with only one case where SSEF was rated

“worse” than SREF. The 0000–0600 UTC SSEF forecasts in Fig. 6 were rated “much better” than SREF. Overall, the SSEF products offered such a large improvement that the HPC forecasters described the SSEF guidance as transformational for warm-season QPF. Although an operational SSEF system is several years away, based on the positive experiment results, the HPC increased the number of experimental CAMs and CAM-derived fields available to forecasters operationally.

HRRR model evaluations. The 3-km High-Resolution Rapid Refresh (HRRR; Alexander et al. 2010) model being developed by NOAA/ESRL/GSD provides 15-h forecasts initialized hourly for users needing frequently updated short-range weather forecasts, including those in the U.S. aviation and severe weather forecasting communities. During SE2010, the HRRR was mainly used for afternoon outlook updates, and particular attention was given to whether the most recent HRRR guidance improved upon earlier HRRR initializations. Intuitively, one would expect

FIG. 10. (a) Simulated 1-km AGL reflectivity (dBZ) at forecast hour 5 (valid 2300 UTC) from the 1800 UTC 17 Jun 2010 initialized HRRR, and (b) corresponding observed base reflectivity (dBZ). (c) As in (a), but for forecast hourly maximum updraft helicity (m^2s^{-2}), and (d) observed storm reports between 2200 and 2300 UTC 17 Jun 2010 (green “A”s indicate hail, blue “W”s and “G”s indicate wind, and red “T”s indicate tornadoes).

later initialized guidance to be improved, but this issue has yet to be examined for such short-range/high-resolution forecasts. Thus, the following survey question involved comparing hourly forecasts of 1-km AGL simulated reflectivity from HRRR forecasts initialized at 1200, 1400, 1600, and 1800 UTC: Is the perceived skill of each subsequent HRRR forecast superior to the preceding forecast? The responses (Q4 in Table 2) were evenly split between later initialized forecasts being better and about the same relative to earlier forecasts. There was one occasion when later HRRR forecasts were found to be worse than earlier ones. The archived comments indicated that improvements in the later initializations were sometimes quite noticeable:

8 June: Each later initialization time seemed to get a better handle on the organization of the MCS that moved into central NE. Specifically, the 1800 UTC initialization had a comma head structure for the forecast valid at 0400 UTC that looked very similar to what was observed, although just slightly displaced.

FIG. 11. As in Fig. 10, but for 3-h HRRR forecasts (valid 2100 UTC) initialized 1800 UTC 18 Jun.

However, improvements in later runs were typically small and/or for specific features. For example,

24 May: The most recent HRRR run (1800 UTC) did slightly better with the SE US convective system. But generally, there wasn't much difference in skill between the different initializations.

15 June: The improvement is only slight with each later initialized forecast, and for only the convective system in East Oklahoma.

Additionally, sometimes later initialized forecasts were improved in certain areas but degraded in others. For example, other comments included:

21 May: Perhaps the later initialized forecasts had a better defined W–E oriented line of convection, which better corresponded to obs. However, later initialized forecasts also added spurious convection in MO and AR.

Figures 10 and 11 illustrate typical good (17 June) and bad (18 June) HRRR forecasts, respectively.

CONCLUDING REMARKS. SE2010 marks the eleventh year of annual Spring Experiments organized

by the SPC and NSSL. These experiments accelerate the transfer of research tools to operations through intensive real-time forecasting and model evaluation activities, and they inspire operationally relevant research initiatives. During SE2010, the traditional focus on severe weather was expanded to include important collaborations with two other NCEP centers to address a wider range of convective hazards. The HPC led an initial effort exploring high-resolution forecasts of precipitation and excessive convective rainfall, and the AWC examined new forecasting tools to improve thunderstorm forecasts for aviation. The three forecasting components operated simultaneously within the HWT.

Detailed information was collected daily to document experimental forecasts, perceived value of model guidance, and subjective model evaluations, including an assessment of newly developed experimental products and display formats. All participants shared in the challenges of making forecasts based on imperfect guidance. Because the weather each day was “live,” no one knew the correct “answer,” which created a sense of realism and operational urgency to the experiment. The next-day evaluation of products was often a humbling and instructive exercise.

The HWT brings together different parts of the meteorological community to work together in real time, addressing a variety of severe weather topics. Given the historically large separation between operational forecasting and research, the HWT provides a relatively rare opportunity for interaction between operational forecasters and/or research scientists on subjects of mutual interest. The HWT has very successfully fostered collaborative research, partially because of the public safety and societal importance of convective weather, but also because the structure of the experiments enables forecasters and researchers to better understand their respective roles. Thus, forecasters gain more knowledge about how research is conducted, and researchers are able

to better understand operational requirements and constraints. In short, all participants are taken out of their respective “comfort zones” when they participate in the HWT, resulting in numerous benefits as a two-way research-to-operations–operations-to-research (R2O–O2R) dialog emerges. Illustrating these mutual benefits, on a scale of 1–10 (1 being “not useful” and 10 being “extremely useful”), nearly 90% of SE2010 participants rated their HWT experience between 8 and 10 for the degree of usefulness in contributing to “. . . unique and valuable perspectives and/or partnerships applicable to your current work and professional activities . . .” Numerous scientific challenges remain for the development of accurate and reliable storm-scale guidance, which requires improvements in data assimilation, models, postprocessing, and forecaster interpretation. The HWT will continue to play a key role in these tasks.

ACKNOWLEDGMENTS. Many individuals contributed to the success of SE2010, including Gregg Grosshans, Jay Liang, Joe Byerly, Linda Crank, and Peggy Stogsdill (SPC); Scott Dembek, Greg Trotter, Brett Morrow, Jeff Horn, Steve Fletcher, Brad Sagowitz, Linda McGuckin, and J. J. Gourley (NSSL); Morris Weisman, Wei Wang, Greg Thompson, and Jimmy Dudhia (NCAR); Matt Pyle, Zavis Janjic, Brad Ferrier, and Geoff DiMego (NCEP/EMC); Stan Benjamin, Steve Weygandt, John Brown, and Curtis Alexander (ESRL/GSD); Barbara Brown, David Ahijevich, Jamie Wolff, Michelle Harrold, Steve Sullivan, and Paul Oldenberg (NCAR–NOAA DTC); Bill McCaul, Jon Case, and Scott Dembek (NASA/SPoRT in Huntsville); Louie Grasso and Dan Lindsey (CIRA); Jason Otkin, Justin Sieglaff, Wayne Feltz, and Jason Brunner (CIMSS); John Mecikalski, Wayne MacKenzie, and John Walker (UAH); and Kris Bedka (NASA Langley). Feedback/recommendations from Tony Eckel (NWS OST) were especially appreciated.

In addition to NOAA CSTAR support, CAPS simulations received supplementary support from NSF Grant ATM-0802888. All 2010 CAPS forecasts were produced at the National Institute of Computational Sciences (NICS) at the University of Tennessee, and Oklahoma Supercomputing Center for Research and Education resources were used for ensemble postprocessing. A National Research Council Post-doctoral Award supported AJC.

Special thanks to the GOES-R Program Office, the NWS, and the NSSL for visitor travel support. We recognize the full support of SPC and NSSL management; the leadership of SPC forecasters in guiding the severe weather component each year; and contributions from many participants who clearly demonstrated the value of collaborative experiments, and whose talents and enthusiasm resulted in a positive learning experience for everyone.

Finally, we thank Matthew Bunkers and two anonymous reviewers for their helpful suggestions, which improved the manuscript.

FREE K-12 Teacher Professional Development Courses

Project Atmosphere

A free summer workshop for K-12 teachers at the NOAA/National Weather Service Training Center in Kansas City, MO. This workshop focuses on sensing, analyzing and forecasting the atmosphere. Earn 3 FREE graduate credits!

Program Dates

July 15-27, 2012

Application Deadline

March 30, 2012

www.ametsoc.org/amsedu/proj_atm

The Maury Project

A free two week K-12 teacher professional development workshop on physical oceanography. The workshop is held at the U.S. Naval Academy in Annapolis Maryland. Earn 3 FREE graduate credits!

Program Dates

July 9-20, 2012

Application Deadline

March 16, 2012

www.ametsoc.org/amsedu/maury

DataStreme Atmosphere, Ocean, and Earth's Climate System

Free semester-long online courses for K-12 teachers in atmosphere, ocean, and climate science! This course teaches you the science, and helps get exiting real-world data into your classroom. Earn 3 FREE graduate credits per course!

For more details and how to apply, visit:

www.ametsoc.org/amsedu
