ABSTRACT

Observed changes in intense precipitation (e.g., the frequency of very heavy precipitation or the upper 0.3% of daily precipitation events) have been analyzed for over half of the land area of the globe. These changes have been linked to changes in intense precipitation for three transient climate model simulations, all with greenhouse gas concentrations increasing during the twentieth and twenty-first centuries and doubling in the later part of the twenty-first century. It was found that both the empirical evidence from the period of instrumental observations and model projections of a greenhouse-enriched atmosphere indicate an increasing probability of intense precipitation events for many extratropical regions including the United States. Although there can be ambiguity as to the impact of more frequent heavy precipitation events, the thresholds of the definitions of these events were raised here, such that they are likely to be disruptive. Unfortunately, reliable assertions of very heavy and extreme precipitation changes are possible only for regions with dense networks due to the small radius of correlation for many intense precipitation events.

1. Introduction

In this paper we present an overview of findings related to changes in very heavy or intense precipitation, changes that are often disruptive to the environment and the economy (Edwards and Owens 1991; Easterling et al. 2000a, b; Soil and Water Conservation Society 2003; more information available online at http://earthobservatory.nasa.gov/NaturalHazards/). We do not focus on particular environmental and/or agricultural thresholds (e.g., floods, landslides, erosion, etc.) to define intense precipitation levels but instead, we use event frequency thresholds. In general, throughout this paper, we count the upper 0.3% of daily rainfall events. This can be equated to a return period of approximately one daily event in 3 to 5 yr for annual precipitation and approximately 10 to 20 yr for seasonal precipitation, depending on the probability of daily rain events for a given location. Regionally averaged frequencies of these events and their changes are calculated using long-term datasets.

The structure of this article is as follows. First, we

1 For a given location and season, we define a daily precipitation event as heavy when it falls into the upper 10% and/or 5% of all precipitation events; as very heavy when it falls into the upper 1% and/or 0.3% of precipitation events; and extreme when it falls into the upper 0.1% of all precipitation events. Therefore, for heavy and very heavy precipitation events, we always specify the specific percentile used to avoid ambiguity.
briefly review previous work and results related to heavy and very heavy precipitation over the land and describe the global network of daily precipitation stations available for analysis. Next, we describe the methodology used in our study and present our most recent results for several countries over the globe, including the contiguous United States. Finally, changes in heavy precipitation from global climate change simulations with changes in greenhouse gases and other forcings from three different global climate models are compared with observed changes.

2. An overview of the past studies

Changes in heavy and extreme precipitation were first documented by Iwashima and Yamamoto (1993) who used the data from scores of stations in Japan and the United States. A more detailed assessment for heavy precipitation increases over the contiguous United States was published by Karl and Knight (1998). Using the data from ~200 long-term stations, Karl and Knight (1998) showed that the sums of the highest monthly daily precipitation events had statistically significant increasing linear trends over four of the nine regions studied over the period 1910–95. Nationwide, there was a 7% increase. At the same time, Karl and Knight (1998) demonstrated that the contribution of the upper 10% of precipitation events to annual totals has increased nationwide. Thus, two important aspects of heavy precipitation were changing, amount and frequency, but the analysis was for a relatively sparse network. When attempts were made to raise the threshold above the 10 percentile, it immediately became obvious that a denser network was required. Section 4b explains theoretical considerations behind this requirement.

Groisman et al. (1999a) assumed a simple and quite flexible three-parameter model for the distribution of daily precipitation totals. The model was tested and fitted to the data of eight countries (Canada, the United States, Mexico, Norway, Poland, the former USSR, China, and Australia), in order to study the sensitivity of the probability of heavy rainfall ($P_{\text{heavy}}$). This was done by varying the model parameters according to their observed temporal and spatial variations as well as by the time series analysis of variations in $P_{\text{heavy}}$. Groisman et al. (1999a) found a disproportionate change in precipitation intensity whenever the mean precipitation changed. This was also shown theoretically by Katz (1999).

These studies and an increasing number of model projections indicate that changes in intense precipitation are more likely as global temperature increases (e.g., Meelh et al. 2000; Cubash and Meehl 2001; Zwiers and Khair 1998; Khair and Zwiers 2000; Allen and Ingram 2002; Semenov and Bengtsson 2002). This has triggered a set of studies to determine the change in the probability of heavy precipitation over the world using all available daily data. Easterling et al. (2000c) summarized these efforts. Thereafter, a number of regional studies have now become available (e.g., Stone et al. 2000; Zhang et al. 2001; Frei and Schär 2001; Alpert et al. 2002; Frich et al. 2002; Roy and Balling 2004). Some basic tenets emerging from analyses include:

- To obtain statistically significant estimates, the characteristics of heavy precipitation should be areally averaged over a spatially homogeneous region. Otherwise, noise at the spatial scale of daily weather systems masks changes and makes them very difficult to detect (e.g., Frei and Schär 2001; Zhang et al. 2004).
- Whenever there are statistically significant regional changes in the rainy season, relative changes in heavy precipitation are of the same sign and are stronger than those of the mean. A search at various sites around the globe using our data holdings and results from others (e.g., Osborn et al. 2000; Tarhule and Woo 1998; Suppiah and Hennessy 1998; Zhai et al. 1999; Groisman et al. 2001) confirm this.
- This search also revealed several regions where mean precipitation does not noticeably change in the rainy season but heavy precipitation does change. In such cases, there was always an increase in heavy precipitation. Among these regions are Siberia, South Africa, northern Japan (Easterling et al. 2000c), and eastern Mediterranean (Alpert et al. 2002).

In the recent report by the U.S. Soil and Water Conservation Society (2003; Tables 1, 2, and 3), changes in

nationwide (contiguous U.S.) annual precipitation with a partition of daily rainfall into heavy (above the 95 percentiles and/or above 50.8 mm), very heavy (above the 99 percentiles and/or above 101.6 mm), and extreme (above the 99.9 percentiles) events were assessed. Tables 1 and 2 showed that as the mean total precipitation and the number of rainy days over the conterminous U.S. increased, the heavy and very heavy precipitation increase was significantly greater, as was the proportion of the total precipitation and counts attributed to these events. Thorough analysis of the United States data indicated that practically the entire nationwide increase in heavy and very heavy precipitation occurred during the past three decades (Table 3).

Groisman et al. (2001, 2004) considered different definitions for heavy and very heavy precipitation and their changes during the past century for the contiguous United States. Groisman et al. (2004) raised the threshold definition of very heavy precipitation events to the upper 0.3% of daily precipitation events. This translates to an 80 mm day$^{-1}$ threshold for daily precipitation in the major agricultural area of the midwestern United States and over 100 mm day$^{-1}$ for the southern and southeastern parts of the United States (Table 4). When selected from a 12-month period, events above the upper 0.3% threshold have a return period of only once in approximately 3 to 5 yr. When selected among a 3-month season of daily events, the return period of very heavy precipitation events varies from 10 to 20 yr, depending upon the total frequency of days with measurable precipitation in the region. For these defined thresholds, Groisman et al. (2001, 2004) found statistically significant century-long trends in the frequency of very heavy precipitation events within three major regions (Fig. 1; the South, Midwest, and Upper Mississippi) of the central United States. These regions are particularly important because they cover most of the Mississippi River basin and most of the wheat and corn belts of the country. Their analysis showed that regionally and seasonally, changes in very heavy precipitation vary significantly, and the magnitude of the trends is most notable in the eastern two-thirds of the country, and primarily in the warm season when the most intense rainfall events typically occur. We extend this work as described in section 5g.

3. Data

Subdaily precipitation time series provide more information about precipitation intensity than daily totals (Trenberth et al. 2003). However, subdaily data are readily available in sufficient quantities only for the contiguous United States (Frederich et al. 1997; NCDC 1998), and homogeneity problems remain to be overcome prior to their use (Groisman et al. 1999b). Therefore, in this study we use daily total precipitation data sets compiled at the National Climatic Data Center (NCDC; Fig. 2; NCDC 2002). Precipitation information is available for virtually all of these stations. Several regions of the world (most of North America, East Asia, eastern Australia, eastern Brazil, India, South Africa, central Mexico, southern half of the former USSR, and Northern Europe) have a sufficiently dense network to make it feasible to study changes in very heavy precipitation. There are many more precipitation sta-

4. Analysis method

The regional averaging technique employed throughout this paper is described in section 4a. Section 4b discusses the representativeness of the area-averaged time series used in this study. In most cases we present the actual time series, which allows the reader to judge the form of systematic trends revealed. We did not focus on the linearity of the changes and used (in addition to the linear trend assessment) a nonparametric test to check for a monotonic change of the time series. In a few cases, when significant nonlinearity was detected, we point it out explicitly. Once a statistically significant trend has been discovered, we characterize it by the mean rate of change. A linear trend estimate is an essential characteristic in this case. We tested the presence of systematic change in the time series using two standard methods: least squares regression (Draper and Smith 1966; Polyak 1996) and a nonparametric method based on Spearman rank order correlation (Kendall and Stuart 1967). We used two-tailed tests at the 0.05 or higher significance level. We tested for autocorrelation of the detrended time series of very heavy precipitation, but the residuals of the frequencies of heavy and very heavy precipitation events were never found to be autocorrelated.

4a. Area-averaging routine

Meteorological stations are not uniformly distributed. Stations tend to cluster around major metropolitan areas and are sparse in mountainous terrain. Missing values are present in most of the records. Both factors had to be addressed to properly represent regional averages of the frequency and/or amount of very heavy precipitation derived from in situ observations. Area-averaged calculations presented in this paper all use the same method. First, we selected a reference period with the greatest availability of data to estimate the long-term mean values for each element and for each season. For most of the countries/regions, the period selected was 1961–90 but, for example, in the Nord-Este region of Brazil the reference period used

### Table 4. Area-averaged annual and seasonal daily precipitation thresholds (in mm) for very heavy (upper 0.3%), and extreme (upper 0.1%) precipitation events in different regions of the contiguous United States. Note that at each specific location the threshold precipitation value may be different. The return period for such events varies depending upon the frequency of days with measurable precipitation and varies, for example, from 3 to 5 yr for annual and 10 to 20 yr for seasonal very heavy precipitation events. Region numbers correspond to those shown in Fig. 1

</table>
was 1951–80 because for a significant number of stations the data ended in 1980. For each station, we determined the empirical distribution function and the set of upper threshold values (90, 95, 99, 99.7, and 99.9 percentiles of rainy day events) for daily precipitation during the reference period. Then, exceedences (or precipitation totals for some analyses) above the threshold values were totaled and the climatological mean was calculated for the threshold based on the reference period. For each region, season, year, and intense precipitation threshold, we calculated the anomalies from the long-term mean number of exceedences (or precipitation totals above the thresholds) for each station and then arithmetically averaged these anomalies within 1° × 1° grid cells. These anomalies were regionally averaged with the weights proportional to their area. Data from the large regions use the regional area weights to form a national average when those analyses are presented. The long-term mean values (normals) were area-averaged in a similar fashion and used to determine actual precipitation amounts. This approach emphasizes underrepresented parts of the region/country because a region, even with a relatively low percentage of grid cells with data will receive the full weight comparable to the region’s area relative to other regions. It also allows the preservation of the regional time series unaffected by the changing availability of data with time.  

In some situations, time series of exceedences of very high climatological thresholds vary substantially between reference periods due to changing climate conditions (Zhang et al. 2005). Special experiments with varying reference periods were conducted to assure that the conclusions presented in this paper are not affected by this problem.

b. Representativeness of regional estimates of very heavy precipitation frequency

1) THEORETICAL FRAMEWORK

Each estimate of the area-averaged anomaly of a variable, $X$, is based on a set of point (or grid cell) measurements of these anomalies, $x_i$ (i = 1, 2, … N), within a region with area $S$. The estimate should be representative of the regional quantity. Formally, this means that a linear combination of our point measurements, $X' = \sum w_i x_i$, should be as close to variable $X$ as possible ($w_i$ are the weights of averaging in approximaton of $X$ by $X'$). The mean square error, $E^2$, of the linear estimate of the area-averaged anomaly $X$ over the region $S$ using data ($x_i$) from $N$ locations (or grid cells) is given by Kagan (1997) as

$$E_2 = \sigma^2 + 2 \sum w_i \Omega_i + \sum \sum w_i w_j R_{ij} + \sum w_i^2 \delta^2,$$  

where $\sigma^2$ is the variance of the variable $X$ averaged over the region $S$, $\Omega_i$ is the covariance of $x_i$ and $X$, $R_{ij}$ is the covariance between $x_i$ and $x_j$, and $\delta^2$ is the variance of the error of measurement at location $i$. If the statistical structure of the $x$ field is known, the error $E^2$ can be estimated for each set of sites (grid cells) inside the region with any selection of $w_i$. Our selection of weights $w_i$ is described in section 4a.

The use of anomalies guards against faulty trends due to station dropouts.
The spatial correlation function of the frequency of very heavy precipitation has never been estimated previously, although it is likely that the radius of correlation of these quantities is quite small. We calculated the spatial correlation function of the seasonal and annual frequencies of very heavy precipitation (our x fields) and approximated it in the form

\[ r(\rho) = C_0 \exp(-\rho/\rho_0), \]

where \( \rho \) is the distance, \( \rho_0 \) is the radius of correlation, and \( C_0 \) is a constant less than or equal to 1. The term \((1 - C_0)\) is an estimate of the portion of the variance of the x field that is not spatially correlated. As a result, \( C_0 \) characterizes both microclimatic variability and errors in x measurements (i.e., \( \delta^2 \)). In our estimates for the contiguous United States, Australia, Brazil, South Africa, and Mexico, \( C_0 \) varies between 0.55 and 1.0.

The relative root-mean-square error, \( Z \), of the mean anomaly of the x field over the region S that is approximated by \( x_i \) at N points (grid cells) evenly distributed over the region S (below we denote the area of the region with the same letter, S) can be described by

\[ Z_S = C_i[(1 - C_0)/C_0 + 0.23(S/N)^{1/2}\rho_0^{-1}N^{1/2}], \]

where the spatial correlation function is approximated by Eq. (2), and \( C_i \) is the coefficient of variation of the x field (Kagan 1997). If the points/cells are not evenly distributed over the region, \( Z_S \) is increased by a factor influenced by the area-averaging routine, the parameters of spatial correlation function, and the measure of unevenness of the station distribution.

Following the area-averaging procedure described in section 4a, we first estimated the representativeness of gridcell area averaging. This step provided us estimates of the accuracy of the \( 1^\circ \times 1^\circ \) grid cell values for the average frequency of heavy and very heavy events. These accuracy estimates were then used for evaluation of the regional \( Z_S \) values.

2) Results

The application of Eq. (3) shows that for the annual frequency of very heavy precipitation events for a typical \( 1^\circ \times 1^\circ \) grid cell on fairly level terrain \(^4\) (with a \( \rho_0 \) of \(~30 \text{ km} \) and \( C_0 \) of \(~0.3 \)), with three, two, or one stations we cannot reduce our error below 10%, 15%, and 25%\(^5\) and a similar assessment in mountainous \( 1^\circ \times 1^\circ \) grid cells \(^6\) (with a \( \rho_0 \) of \(~10 \text{ km} \) and \( C_0 \) of \(~0.4 \)) gives estimates of \( Z_S \) in the range of 25%, 35%, and 60%, respectively.\(^7\)

The appendix Table A1 provides estimates of \( \rho_0 \) and \( C_0 \) for the frequency of heavy (H) and very heavy (VH) seasonal and annual precipitation (above the upper 10 and 0.3 percentiles, respectively) for several regions of the contiguous United States and two regions of the European part of the former USSR. In the latter, thunderstorm activity associated with very heavy precipitation is less spatially expansive compared to the former (i.e., it rarely manifests itself as a multicell event) and we rarely have more than one station per grid cell. Consequently, here we obtained estimates of \( C_0 \) below 0.5 for approximations of the spatial correlation function of the frequency of VH annual precipitation events between \( 1^\circ \times 1^\circ \) grid cells. Large values of seasonal and annual radius of correlation for frequency of heavy precipitation events of several hundred kilometers (up to 600 km in the northwestern United States in winter) assure the representativeness of area-averaged values of this quantity based on a point/gridcell network similar to that for mean seasonal/annual precipitation (cf. Czelniak et al. 1963; Huff and Changnon 1965; Kagan 1997). For VH events, further analysis was required.

In a region larger than a grid cell (e.g., the midwestern United States, which encompasses \( 82 \times 1^\circ \times 1^\circ \) grid cells, with nearly complete gridcell data coverage during the entire twentieth century Fig. A2), we obtained \( Z_S \) less than 2% throughout the twentieth century for the area-averaged annual VH frequency. In this region, \( Z \) values remain less than 3% even in the last decade of the nineteenth century. The opposite situation (among the regions considered in this paper) is evident in northwestern Russia between 60°N and the Arctic Circle. This region, with area \(~10^6 \text{ km}^2 \), does not have a complete (or nearly complete) \( 1^\circ \times 1^\circ \) grid cell coverage to start with (Fig. A3). Fifteen \( 1^\circ \times 1^\circ \) grid cells with data (usually a single station within a cell and the cells unevenly distributed over the region) result in a value of \( Z_S \) close to 15%. The term \( C_i[(1 - C_0)/C_0 - N^{-1} + \ldots]^{1/2} \) is a major component in Eq. (3) for this region and it decreases slowly with increasing \( N \). The above illustrates that the number of \( 1^\circ \times 1^\circ \) grid cells with valid station data is an important component in the accuracy of area averaging. Therefore, this quantity was used throughout the study to control the level of representativeness of our results for each region discussed below.

\(^4\) For example, the midwestern United States, European Russia, or Australia.

\(^5\) We consider the \( Z_S \) estimates to be on a low side because of several assumptions [e.g., that the stations are distributed evenly over the grid cell, that the approximation of the covariance function, \( R \), with the help of Eq. (2) is precise, etc.] in reality do not materialize and/or are only convenient approximations.

\(^6\) For example, the southwestern or northwestern United States, Caucasus, or Mexico with large micrometeorological variability.

\(^7\) The use of frequencies of intense precipitation with thresholds derived from the local distributions may not be very different at low and high elevations, because we are flexibly changing the definitions of heavy events. This alleviates to a certain extent the impact of the elevation-inhomogeneous distribution of stations that interferes with steep precipitation gradients. But, in the mountains, assumptions of implementation of Eq. (2) (in particular the isotropy of the spatial covariance function, \( R \)) are less reliable than on the plains (Gandin et al. 1976; Gandin 1988). This adds additional uncertainty and indicates that the \( Z_S \) estimates are to be on a low side.
3) A major concern

Scattered thunderstorms in the area, or strong gradients in precipitation totals and/or variances (e.g., due to elevation changes) may cause a fraction of the rain events to remain unnoticed and/or the estimates of the area total to be biased. For example, in the contiguous U.S. west of 105°W, the mean average elevation of the synoptic station network is about 500 m below the mean elevation of the surface and most of the cold season precipitation is orographically defined (Daly et al. 1994). To avoid biases associated with spatial inhomogeneity in the mean and variance of the field, we analyzed anomalies and used point-defined individual thresholds and counts above these thresholds. The use of counts (instead of actual values of precipitation) gave us more robust results even when we do not have a dense network. For example, if we have widespread heavy rain events that fall mostly in the mountains, while only their remnants show up in the valley where our station happens to be located, then we may still capture these events and our count of the heavy and/or very heavy events is still unbiased. Problems arise for small $p_0$ (e.g., scattered thunderstorms) and a relatively sparse network that cannot capture most of these events. Biases, however, are not a major concern in this situation. Let us assume that the network is so sparse (or $p_0$ is so small) that each event is counted only once (i.e., only at one station). Then the area-averaged count of the events according to our area-averaging routine will be equal to the count of events divided by $N$ and remains the estimate of the probability of the event at a single station within the region. If we assume the statistical field to be isotropic with a spatial covariance function provided by Eq. (2), this will still be an unbiased estimate of the average probability of this type of event within the region. However, if $N$ is small, the estimate will be of very low accuracy. This immediately would be noticed by the second term in $Z_s$ [Eq. (3)], which would grow to very high values. When $Z_s$ becomes greater or comparable to $C_u$, the practical importance of our area-averaged estimate based on the point measurements in that particular instance becomes low and the information carried by the measurements is not clearly seen beyond the noise level. Moreover, one can select an alternative network within the same region, which will provide alternative estimates that are independent (uncorrelated) with those produced by the original network. Thus, for the processing and analyses applied to this study, it is not biases but representativeness that is the key problem. Empirically, we observed the manifestation of this problem in the portion of the regionally averaged time series that is based on an insufficiently dense network. The interannual variability of this portion starts behaving badly. It become highly variable compared to the period with sufficiently dense network in the region (cf. Osborn and Hulme 1997) meaning that the variability of the time series was dominated by the random error of the estimation process.

5. Analyses for several regions in the world

a. European part of the former USSR

For this region, more than 700 long-term stations during the period 1936–97 are available for analyses of heavy and very heavy precipitation (Bulygina et al. 2000). The numbers of stations for the two regions under consideration shown in Fig. 3 are 70 and 633. In general, maximum precipitation in this area occurs during the warm season, with very heavy rainfall coming almost entirely from convective clouds (Sun et al. 2001). Note that approximately 95% of the daily precipitation events are less than 10 mm day$^{-1}$. Table 5 and Figure 3 summarize the results of trend analyses for these two regions. Both show a large increase of 10% to 15% in annual precipitation in the region for the study period although the century-long increase is smaller (e.g., Groisman 1991; Groisman and Rankova 2001). During the same period, the rates of increase in heavy precipitation, in very heavy precipitation, and in extreme rainfall were higher than for mean annual precipitation. The linear trend of the time series of heavy precipitation was statistically significant at the 0.01 level in both regions. In the southern region, trends in very heavy (upper 1% of rain events) and even in extreme precipitation are statistically significant at the 0.05 level or above. The trends of very heavy precipitation in the north are not statistically significant, partly due to large sampling errors resulting from a small number of stations in that area (Figs. 1 and A3). The network here is adequate for capturing total precipitation and the upper 10% and 5% of precipitation events. However, when totaling the precipitation of rare very heavy rain events (that occur once per year or even less frequently), one needs a denser network to suppress the very high weather variability associated with these events. The $Z$ estimates based on Eq. (3) show that the random errors of the area-averaged frequency of very heavy and extreme precipitation are approximately 4 times higher than in the southwestern part of the former USSR.

b. Northern Europe

Fennoscandia is very well covered by precipitation stations (Groisman and Legates 1995), but only a fraction of the daily data for this network is available publicly (Klein Tank et al. 2002), or for special research projects such as Arctic Climate Impact Assessment (ACIA 2004; Groisman et al. 2003). In the framework of ACIA, a study of contemporary climatic changes in high latitudes during the past 50 yr has been conducted (Groisman et al. 2003). To define heavy precipitation events in high latitudes, a special effort was made to
separate and further consider only discernible precipitation events, which we have defined as those above 0.5 mm. The reason for this is that the median of daily precipitation events over most regions in high latitudes is close to or even less than 0.5 mm. This coupled with the frequently changing precision of measurements can interfere with our analyses, for example, in Canada and Norway (Groisman et al. 1999a). There were previous reports describing the total precipitation increase in northern Europe (Groisman 1991; Hanssen-Bauer et al. 1999).

**Fig. 3.** Annual (pluses), heavy (upper 5%; squares), and very heavy (upper 0.3%; triangles) precipitation totals over the western half of the former USSR (regions of area averaging are shown darkened in the maps within the plots) and their linear trends (solid lines). Statistical significance of linear trends is provided in Table 5. The numbers of 1° × 1° grid cells with valid station data are shown by dotted lines.
1997; Heino et al. 1999; Førland and Hanssen-Bauer 2000; Folland and Karl 2001), but they all reported a smaller relative change compared to our results for changes in very heavy precipitation frequency both in summer (a season with the most intense precipitation) and throughout the year (Fig. 4).

c. Pacific coast of northwestern North America

This is the only large high-latitude region with both large annual precipitation totals and a sufficiently dense precipitation network available for our analyses. Figure 5 shows the time series of the frequency of heavy and very heavy precipitation in southern Alaska (south of 62°N) and British Columbia, Canada (south of 55°N). In both regions, precipitation increased during the period of record, but the double-digit increase in the frequency of heavy and very heavy precipitation is especially noteworthy (Table 6). Given the high thresholds for these events, these changes reflect an increasing societal and/or environmental threat in both areas.

d. Southeastern and southwestern Australia

Southeastern Australia is densely populated and thus is well covered by a long-term precipitation network (Lavery et al. 1997; Fig. A4). The southwestern tip of the continent has good station coverage since the mid-1910s. Precipitation occurs in southeastern Australia year round without particular peaks in the seasonal cycle while a winter (June–August) maximum is observed in the southwest. The regionally averaged thresholds for annual very heavy precipitation (upper 0.3% of daily events) are 82 and 53 mm, respectively. Figure 6 shows time series of both annual precipitation and the frequency of days with very heavy precipitation for these two regions. Precipitation totals increased by 16% (100 yr)$^{-1}$ in the southeast and decreased by the same amount in the southwest during the period with sufficient data (1907–98 and 1913–98, respectively). The 52% (100 yr)$^{-1}$ increase in frequency of very heavy precipitation in the southeast is statistically significant at the 0.05 level, while the 43% (100 yr)$^{-1}$ decrease in the southwest is statistically significant only at the 0.10 level.

e. South Africa

We focused on the eastern part of the country, which is more humid and is mostly farmland. This area is thoroughly covered by a dense, long-term precipitation network (Fig. A5). The regionally averaged thresholds for very heavy precipitation in the upper 0.3% of daily events for annual and summer (December–January–

Fig. 5. Heavy and very heavy annual precipitation variations and linear trends along the northwestern coast of North America (a) British Columbia south of 55°N and (b) Alaska south of 62°N. Statistical significance of linear trends is provided in Table 6.
February, hereafter DJF) are 85 mm (return period 5 yr) and 90 mm (return period 10 yr), respectively. Figure 7 shows time series of both precipitation totals and frequency of very heavy precipitation for this region. While annual and summer precipitation totals did not change during the period with sufficient data (1906–97), there is an increase in the annual frequency of very heavy precipitation that is statistically significant at the 0.05 level. These results broadly correspond to those by Fauchereau et al. (2003). In addition, we noted a significant increase in very heavy precipitation during the last three decades (a feature that was also evident for the contiguous United States; cf. Groisman et al. 2004; section 5g).

f. Eastern Brazil and Uruguay

A sufficiently dense network for the past 70 yr is available for the eastern half of Brazil and Uruguay (Figs. 2 and A6). This became possible after the National Meteorological Service, in cooperation with the private company Agência Nacional de Energia Elétrica (ANEEL) made their national precipitation data publicly available online. An explosion of research resulted (Liebmann et al. 1998, 1999, 2001; Liebmann and Marengo 2001; Marengo et al. 2001; Carvalho et al. 2002).

Figure 8 shows time series of both annual precipitation and the frequency of very heavy precipitation for three regions of eastern Brazil and Uruguay. For these three regions, the regionally averaged thresholds for annual upper 0.3% of daily rainfall events are 100, 95, and 120 mm, respectively, and have return periods of 3 to 4 yr. Very high precipitation variability in a relatively dry climate of the Nord-Este is modulated by El Niño–La Niña events (Ropelewski and Halpert 1996). In the Nord-Este, we found a statistically significant increase in the annual frequency of very heavy precipitation events of 40% (100 yr)$^{-1}$, but all of the increase occurred during the first half of the twentieth century. In the subtropical part of Brazil there was a systematic increase of very heavy precipitation since the 1940s. In the northern subtropical region, where an extremely dense network of São Paulo state was used in our analysis (cf. Liebmann et al. 2001), we obtained an increase of 58% (100 yr)$^{-1}$, or by 34% for the period of record, statistically significant at the 0.01 significance level.

g. Central United States

In three large neighboring regions in the central United States (hatched in Fig. 1), statistically significant increasing trends in very heavy precipitation were documented for the period 1908–2002 (Groisman et al. 2004). Data availability restricted Groisman et al. (2004) in the nationwide analyses of the very heavy precipitation and the frequency of very heavy precipitation for three regions of eastern Brazil and Uruguay. For these three regions, the regionally averaged thresholds for annual upper 0.3% of daily rainfall events are 100, 95, and 120 mm, respectively, and have return periods of 3 to 4 yr. Very high precipitation variability in a relatively dry climate of the Nord-Este is modulated by El Niño–La Niña events (Ropelewski and Halpert 1996). In the Nord-Este, we found a statistically significant increase in the annual frequency of very heavy precipitation events of 40% (100 yr)$^{-1}$, but all of the increase occurred during the first half of the twentieth century. In the subtropical part of Brazil there was a systematic increase of very heavy precipitation since the 1940s. In the northern subtropical region, where an extremely dense network of São Paulo state was used in our analysis (cf. Liebmann et al. 2001), we obtained an increase of 58% (100 yr)$^{-1}$, or by 34% for the period of record, statistically significant at the 0.01 significance level.
precipitation prior to the 1908 starting year. This, however, is mostly due to a data deficiency in the western part of the country (Fig. A2). Here, we extend our analyses of very heavy precipitation back to 1893 (Fig. 9). In 1893, the analysis covers only 84 $1^\circ \times 1^\circ$ grid cells compared with more than 330 during the second half of the twentieth century. This deficiency adds some noise to the regionally averaged time series. Over the study period (1893–2002) the frequency of very heavy precipitation has increased by 20% (statistically significant at the 0.01 level). All of the increase has occurred during the last third of the century (Fig. 9). The longer the time series are, the better is our understanding of the variability of heavy and very heavy precipitation in the twentieth century. But, it is probably a paradox that so much effort was made to collect, quality control, pre-

![Fig. 7. Annual and summer (DJF) rainfall (solid lines) and frequency of very heavy rains (dashed lines) over the eastern half of South Africa (region of area averaging is shown darkened in the map). The linear trend estimates for an increase in the annual and summer frequency of very heavy precipitation [44% (100 yr)$^{-1}$ and 42% (100 yr)$^{-1}$] are statistically significant at the 0.05 and 0.10 levels, respectively.](image1)

![Fig. 8. Linear trend estimates for increases in the annual frequency of very heavy precipitation in the Nord-Este (1911–2001) and northern sub-tropics (1941–2001) are statistically significant at the 0.05 level or higher.](image2)
process, and analyze data for the full 110 yr, only to reveal that during the first 80 yr no systematic changes occurred in very heavy precipitation frequency (Table 3; Fig. 9). However, this emphasized that the change over the last 30 yr is unusual and is (at least for the contiguous United States, South Africa, and central Mexico; cf. Fig. 7; Fauchereau et al. 2003; and the next section) a relatively new phenomenon.

h. Central Mexico

Central Mexico is reasonably well covered with precipitation data for the past 60 yr (Figs. 10 and A7). The North American monsoon is the major cause of summer rainfall away from the coastal areas in the central part of the country. Figure 10 shows that during the past 30 years a substantial precipitation decrease has occurred over the Central Plateau of Mexico. The frequency of heavy precipitation events (those above the 25 to 35 mm thresholds in this region) generally followed the tendency of the mean totals (although these changes were statistically insignificant). However, the frequency of very heavy precipitation (above the upper 1% and 0.3% of the rain events or above 55 and 75 mm, respectively) increased during the same 30-yr-long period. The frequency of very heavy rain events (above the upper 0.3%) has increased substantially [by 110% (30 yr)−1]. Thus, while in the early 1970s the average return period of such events was approximately 12 yr, in the early 2000s it is estimated to be around 5 yr.

i. Summary of observed trends in heavy and very heavy precipitation

Figure 11 is a substantial update of the map from Easterling et al (2000c) where signs (+ and −) show the regions with changes in heavy precipitation found in our studies and in the studies of others that follow the pattern outlined above: changes in mean precipitation are less or insignificant while changes in heavy/very heavy precipitation are statistically significant. The shaded regions in this figure are results from our work, although others have studied some of these regions as well and reached similar conclusions, for example, Stone et al. (2000) for Canada, Iwashima and Yamamoto (1993) for Japan, Roy and Balling (2004) for India, Osborn et al. (2000) for the United Kingdom, Tarhule and Woo (1998) for Nigeria, Zhai et al. (1999, 2005) for China, Kunkel et al. (1999) and Kunkel (2003) for the United States,8 Alpert et al. (2002) for eastern...
Mediterranean, and Haylock and Nicholls (2000) for Australia.

6. Model projections

What are the causes of all the observed trends in intense precipitation? Unfortunately, observed data and/or their analysis alone cannot provide answers to this question. These questions are better addressed by physical models of the global climate system. Precipitation is a variable that is more difficult to simulate than other meteorological variables (McAvaney et al. 2001). Most global climate models project an increase in precipitation intensity with global warming (Schaer et al. 1996; Jones et al. 1997; Hennessy et al. 1997; Mason and Joubert 1997; Zwiers and Kharin 1998; Meehl et al. 2000; Kharin and Zwiers 2000; Cubash and Meehl 2001; Wilby and Wigley 2002; Allen and Ingram 2002; and Hegerl et al. 2003, 2004). Recently, Karl and Trenberth (2003) showed that even without change in total precipitation, there was an increase in the frequency of intense daily precipitation when comparing warmer with cooler climates. There are physical explanations for the reason that changes in heavy precipitation should be more pronounced than changes in precipitation totals in ongoing climatic change (Trenberth 1999; Groisman et al. 1999a; Bengtsson 2001; Allen and Ingram 2002; Trenberth et al. 2003). These explanations will be further discussed in section 7.

Climate models simulate a global-scale increase in mean precipitation due to increased greenhouse gases (Cubash and Meehl 2001). Changes in global mean annual precipitation from an ensemble of coupled model simulations driven by both natural (changes in volcanism and solar forcing) and anthropogenic forcing closely follow the observed trajectory (Allen and Ingram 2002). However, this similarity is caused only by the effect of volcanic eruptions on global precipitation and the anthropogenic signal cannot presently be detected (Lambert et al. 2004; Gillett et al. 2004). Furthermore, the spatial patterns of annual precipitation change are very model-dependent and poorly correlated between different models at the time of the CO₂ doubling (Cubash and Meehl 2001; Hegerl et al. 2004). However, simulated changes in heavy and very heavy precipitation tend to become more positive and stronger than in mean precipitation (Allen and Ingram 2002; Semenov and Bengtsson 2002). The spatial pattern of changes in heavy precipitation shows more regions of increase than the pattern of annual precipitation changes, and hence more similarity between models (Figs. 12–14). This finding of a more consistent pattern of increase in heavy precipitation in climate model simulations is supported by a comparison of two global circulation model (GCM) projections of the warming effects on precipitation associated with the doubling of CO₂ in the atmosphere. Hegerl et al. (2003, 2004) assessed projected changes at the time of CO₂ doubling, but here we highlight additional results from that experiment for North America. The pattern of the difference for annual precipitation and various indices of heavy and very heavy precipitation were analyzed between the “average climate” for the 20 yr 2040–60 in
the $2 \times \text{CO}_2$ simulation (doubled CO$_2$ achieved in latter half of the twenty-first century), and conditions at the end of the twentieth century. This was done for three-member ensemble simulations for each of two models:

- The Canadian Climate Centre model CGCM1, which is the first version of the coupled climate model from the Canadian Centre for Climate Modelling and Analysis (CCCma; Flato et al. 2000; Boer et al. 2000a, b). The atmospheric component of this model has a resolution of $3.75^\circ$ latitude $\times 3.75^\circ$ longitude.

- The third cycle of the Hadley Centre climate model (Gordon et al. 2000; Pope et al. 2000; Johns et al. 2002; see also Stott et al. 2001). This model has the same longitudinal resolution and a higher latitudinal resolution of $2.5^\circ$.

While the historic change in atmospheric composition for non-greenhouse-gas anthropogenic forcing is implemented differently in both models, it is expected that by the middle of the twenty-first century, differences between both ensembles will be largely due to differences in the model response. These two coupled climate models show reasonably realistic five-day extreme rainfall compared to observational and/or reanalysis products (Kharin and Zwiers 2000; Hegerl et al. 2004). The errors and uncertainties are larger in the Tropics, where, despite substantial differences in climatological mean and extreme rainfall, both models simulate moderately similar changes in extreme rainfall, with global mean land precipitation changes in anthropogenic climate change simulations being reasonably similar between the models (Hegerl et al. 2004).

Figure 12 compares the change in annual total precipitation and in the number of exceedences of the 99.7 percentile in two climate models. The comparison re-

---

10 For signal detection purposes, the use of the earlier period as reference period, which is less affected by an anthropogenic increase in greenhouse gases concentrations, would be preferable. However, the end of the twentieth century was selected as reference period in this study (as well as in Hegerl et al. 2004), because much more station data are available at that time. This facilitated the comparison between model simulated and observed trends.

11 Changes in the second version of this model (CGCM2) were quite similar and, therefore, are not assessed here.
veals how inconsistent the pattern of total precipitation changes is compared to that of the change in the frequency of the wettest days in the model output records. Both models show a pronounced pattern of changes of opposite signs with a global mean precipitation increase of between 1% and 2% (Fig. 12; Hegerl et al. 2004), but these patterns correlate poorly between the models. When the change in the upper 0.3% of precipitation events is studied, both models show an increase in precipitation extremes over most regions of the globe, although regional details still differ (Fig. 12). When compared to observed changes in very heavy precipitation reported in this study (Fig. 11), both GCMs predict increases in very heavy precipitation in Siberia, Fennoscandia, central and eastern Europe, southeastern Australia, the northwestern coast of North America, northern Canada, and central Mexico in agreement with the sign of the observed trends. However, both GCMs predict a decrease in very heavy precipitation in South Africa contradicting the sign of the presently observed trends.

Figure 13 shows the “consensus” climate change pattern for the annual mean precipitation over North America. The pattern is based on the average of both model’s simulations. Values are plotted only where the changes in both models are consistent (i.e., the changes in the ensemble simulations with both models at a grid box are not significantly different at the 90% level based on a Mann–Whitney rank test). This represents a pattern of precipitation change that is robust between both models. The difference is striking in this consensus intercomparison. Over most of the continent the change, often even the sign of change in total precipitation, is different between both models (Fig. 13). In a different way, the consensus change in precipitation on the wettest day per year and (to a lesser extent) in the wettest five consecutive days per year, precipitation increases everywhere over North America (Fig. 14). This increased similarity in the patterns of change should lead to a more robust signal in heavy rainfall compared to annual mean precipitation. A simple detection analysis using model data suggests that changes in extreme rainfall may therefore be more robustly detectable than changes in annual total rainfall (Hegerl et al. 2004). By the time of CO$_2$ doubling, annual total rainfall changes simulated in one model could not be reliably detected using fingerprints of climate change based on the other model, while changes in heavy rainfall could be confidently detected by that time between the model simulations. If this finding based on two models can be generalized, it suggests that observed changes of very heavy precipitation are easier to detect and attribute to global warming than changes in the mean annual or seasonal precipitation.

The results based on GCMs are more credible when simulated variability and trends roughly correspond to
those observed during the past century. Unfortunately, the direct intercomparison of transient climate change in heavy precipitation as reproduced by the GCM and the observed change is not a frequent exercise and is hampered by differences in the scale represented by model data (smooth grid boxes) and observed station indices. One such example is presented and discussed below.

In their assessment of heavy rainfall changes in the transient greenhouse gas simulation using a coupled atmosphere–ocean global circulation model (ECHAM4/OPYC3 for 1900–2099), Semenov and Bengtsson (2002; their Fig. 4) looked at results of the simulated changes of the contribution of the upper 10% quantile of daily precipitation to the annual total precipitation over the contiguous United States for the twentieth century. These were compared with the empirical results of Karl
and Knight (1998). A close resemblance of positive trends, mean values, and the amplitude of the inter-decadal variability suggests that the observed changes are in part related to an increase in greenhouse gases. The only other region of the United States that was assessed by Semenov and Bengtsson (2002) was the northeastern quarter of the country, which roughly corresponds to the Northeast and Midwest regions used in the study conducted by Groisman et al. (2004).

Figures 15 and 16 show the changes in the number of days with heavy precipitation and wet days in the eastern United States from model results (Semenov and Bengtsson 2002) and observations (Groisman et al. 2004). Comparing observations in this region with changes in the number of days with heavy precipitation from this model, we did not expect that year-to-year variations in the GCM simulation and observations would coincide. Moreover, the model grid cells generate precipitation twice as frequently as observed in point observations. However, this comparison reveals a similar increase of approximately 10% over the twentieth century in both time series. This model projects a substantial increase (up to 40% to the end of the twenty-first century) of days with heavy precipitation. In spite of the above-mentioned similarities, these are obviously two very different estimates of climate change over the northeastern United States. For example, a century-long change during the twentieth century was shown during the first 70 yr in the model simulation, while the opposite is true in observations. This points to the need for ensemble assessments of future climate projections (Kattsov and Walsh 2000; Kharin and Zwiers 2002).

It is clear that if mean precipitation does not change appreciably compared with the highest part of the precipitation distribution, then the frequency of precipitation events will be affected. Indeed, in several regions of the world this appears to be the case. For instance, in South Africa, Siberia, eastern Mediterranean, central Mexico, and northern Japan, an increase only in heavy and/or very heavy precipitation is observed while total precipitation and/or the frequency of days with an ap-

![Fig. 15. Frequency of the upper 10% of rainy days over the northeastern quadrant of the contiguous United States. (top) Observations (Northeast and Midwest regions; regions 4 and 8 in Fig. 1) for 1908–2002. Annual values (triangles), 10-yr running mean values (solid line), and linear trend (dotted line) are shown. Linear trend for 1908–2002 [12% (100 yr)$^{-1}$] is statistically significant at the 0.05 level. (bottom) ECHAM4 (35°–45°N; 75°–85°W; adapted from Semenov and Bengtsson 2002) 10-yr running mean values for 1900–2090.]
preciable amount of precipitation (wet days) are not changing and/or are decreasing (Figs. 7 and 10; Sun and Groisman 2000; Easterling et al. 2000c; Alpert et al. 2002). The first indication that this feature might also be present in the contiguous United States is shown in Fig. 16 for the northeastern part of the country. Observations show that the annual number of wet days has increased during the past 100 yr, but during the last 30 yr (exactly at the time when most of increase in very heavy precipitation started) a decrease in the number of wet days was observed. This figure is presented to compare the observations with the variations of the regional number of wet days reproduced by the ECHAM4/OPYC3. We see a similarity of tendencies and a very strong decrease in the wet-day frequency projected for the twenty-first century by the model. However, once again the reliability of the model simulation is somewhat hampered by an exaggerated number of days with model-generated precipitation (on average annually, 240 of modeled days are wet, which is much higher than observed).

7. Discussion

A physical explanation for an increase in heavy precipitation with global warming is provided by Trenberth et al. (2003). An expanded body of evidence for the twentieth century presented in this paper appears to support this concept for very heavy precipitation as well. Global warming, which has been especially pronounced during the recent decades in extratropical land areas and in minimum temperatures (Karl et al. 1991; Folland and Karl 2001), is related to a reduction in spring snow cover extent (Brown 2000; Groisman et al. 1994, 2001), and thus to an earlier onset of spring- and summerlike weather conditions (Easterling 2002). Warming also relates to a higher water vapor content in the atmosphere (Douville et al. 2002; Trenberth et al. 2003), which has been documented in many regions of
the world (Sun et al. 2000; Ross and Elliott 2001). This in turn results in an increase in the frequency of Cumulonimbus clouds [documented for the former USSR and the contiguous United States by Sun et al. (2001)], which is related to the general increase in thunderstorm activity [documented for most of the contiguous United States by Changnon (2001)]. This development can explain an observed widespread increase in very heavy precipitation in the extratropics. Furthermore, in humid regions an increase in summer minimum temperatures is related to an increase in the probability of severe convective weather (Dessens 1995) and is likely related to changes in the frequency of heavy and very heavy rain events. It is difficult to directly relate estimates of changes in very heavy precipitation with flooding (e.g., Groisman et al. 2001; Kunkel 2003). However, great floods have been found to be increasing in the twentieth century (Milly et al. 2002).

We are confident in our finding that very heavy precipitation has increased during the period of instrumental observations over most of the contiguous United States. Characteristics used to define very heavy precipitation (frequencies) are robust and have an advantage of being insensitive to scaling errors. Clearly, more work is needed, but the evidence is growing that the observed historical trends of increasing very heavy precipitation are linked to global warming. Simulated changes in intense precipitation and precipitation extremes are generally greater than in mean precipitation and are consistent among the models studied here. It is likely that changes in heavy precipitation will probably be more easily detected than changes in annual mean precipitation in the future climatic changes.

8. Summary and conclusions

An empirical assessment of observed changes of the characteristics of intense precipitation (mostly, the frequency of very heavy precipitation defined as the upper 0.3% of daily precipitation events), and analysis of the output of three GCM simulations with transiently increasing greenhouse gases during the twentieth and twenty-first centuries have been conducted for over half of the land area of the globe (Fig. 11). In summary, these are the major findings:

- Reliable assertions of very heavy and extreme precipitation changes are possible only for regions with dense networks due to a small radius of correlation for most of intense precipitation events.
- In the midlatitudes, there is a widespread increase in the frequency of very heavy precipitation during the past 50 to 100 yr.
- By raising the thresholds for the definition of very heavy precipitation and providing empirical evidence of changes in the frequency of these events, we can better provide a basis for impact assessments of the consequences of these changes, including landslides, floods, and soil erosion.
- Three model projections of a greenhouse-enriched atmosphere and the empirical evidence from the period of instrumental observations indicate an increas-

![Fig. A1. Present coverage of North America south of 55°N with long-term (at least 25 yr of data) stations. Red and blue dots show stations with ~100 and 80 yr of data, respectively. Green dots indicate stations with at least 25 yr of data during the 1961–90 period. Black dots show additional long-term Mexican stations that are presently undergoing extensive quality control.](image-url)
The probability of heavy precipitation events for many extratropical regions including the United States.

Acknowledgments. NASA Grant GWEC-0000-0052 and the NOAA Climate and Global Change Program (Climate Change and Detection Element) provided support for this study. GCH was supported by NSF Grant ATM-0002206 and ATM-0296007, and by NOAA Grant NA16GP2683. DRE and TRK were partially supported by the Office of Biological and Environmental Research, U.S. Department of Energy. Thoughtful comments and suggestions of two anonymous reviewers are highly appreciated.

Table A1. Parameters of statistical structure of the fields of regional frequency of heavy (above the upper 10 percentile) and very heavy (above the upper 0.3 percentile) seasonal precipitation events over the contiguous United States and the European part of the former Soviet Union. Parameters of the spatial correlation function in Eq. (2) \( \rho_0 \) and \( C_0 \) and variance coefficient, \( C_v \), of the 1°-gridcell-averaged values of the frequencies are presented.

Fig. A2. Data availability over the contiguous U.S. generalized within the 1° × 1° grid cells for the periods of a near-constant network. The regional partition of the country used throughout this paper for area averaging is also shown. Counts of stations with more than 50% of daily precipitation data within each grid cell for the (a) 1891–1900, (b) 1901–10, (c) 1911–20, and (d) 1951–2002 periods, respectively.
APPENDIX

Availability of Long-Term Stations

Figure A1 shows the availability of long-term stations in North America used in this study. It can be noted that for most of the contiguous United States there is a sufficient number of century-long daily precipitation time series available. The following set of similar figures (Figs. A2–A7) provide counts of stations with precipitation data within each 1° × 1° grid cell for periods with relatively stable networks for regions used in this study. A station was considered present during the listed period when it had at least 50% of daily precipitation data within it. The figures also depict the regions used for area averaging for the contiguous United States, former USSR, Australia, South Africa, Brazil, and Mexico. Area averaging can be counterproductive and even misleading when changes of opposite signs have occurred within the region. Therefore, we first selected regions that can be considered as relatively climatologically homogeneous according to independent criteria and then applied the area-averaging routine. To preserve the comparability of results, the regional partition for the conterminous United States remains the same as used in Karl and Knight (1998) and Groisman et al. (2001, 2004). When no published climate regions could be found for a country (e.g., South Africa, Brazil, and Mexico), we created them using a combination of climate classifications from Trewartha [available on line at http://fp.arizona.edu/khirschboeck/climate/Trew.map.large.htm], plots of seasonal precipitation averages, and considerations of terrain, vegetation, latitude, and data availability.

Fig. A3. Same as Fig. A2, but over the former USSR for the (a) 1901–10, (b) 1931–40, (c) 1941–50, and (d) 1951–96 periods, respectively.

Fig. A4. Same as Fig. A2, but over Australia for the (a) 1901–10, (b) 1911–20, and (c) 1951–99 periods, respectively. When creating the climate regions for the continent, we primarily used the climate zones based upon rainfall published by the Australian Bureau of Meteorology [available online at http://www.bom.gov.au/lam/climate/levelthree/ausclim/zones.htm]. The regions were modified somewhat using plots of the seasonal precipitation cycle and data availability considerations.
FIG. A5. Same as Fig. A2, but over South Africa for the (a) 1901–10, (b) 1921–30, and (c) 1931–97 periods, respectively. Three climatological regions were selected by taking into account the seasonal precipitation cycle. In the eastern half of the country the precipitation maximum is observed in austral summer (DJF) while along the Atlantic coast it is observed in winter. The desert region between the two has an annual precipitation of ~250 mm.

FIG. A6. Same as Fig. A2, but over Brazil for the (a) 1911–20, (b) 1941–50, and (c) 1951–2001 periods, respectively. The Nord-Este region has an autumn (March–May) precipitation maximum and two extratropical regions have a summer precipitation maximum (DJF). The southernmost region was expanded beyond the national borders to include Uruguay and adjacent small areas of Argentina and Paraguay, which were also well covered by the observations in our dataset.

FIG. A7. Same as Fig. A2, but over Mexico for the (a) 1941–50 and (b) 1951–2002 periods.
