ABSTRACT: Satellite and reanalysis products are used to study the atmospheric environment, aerosols, and trace gases in smoke plumes over South America in the period 2000–18. Climatic conditions and fire density maps provide context to link biomass burning across the southern Amazon region (5°–15°S, 50°–70°W) to thick near-surface plumes of trace gases and fine aerosols. Intraseasonal weather patterns that underpin greater fire emissions in the dry season (July–October) are exacerbated by high pressure over a cool eastern Pacific Ocean, for example in September 2007. Smoke-plume dispersion simulated with HYSPLIT reveals a slowing of westward transport between sources in eastern Brazil and the Andes Mountains. During cases of thick smoke plumes over southern Amazon, an upper ridge and sinking motions confine trace gases and fine aerosols below 4 km. Long-term warming, which tends to coincide with the zone of biomass burning, is +0.03°C yr⁻¹ in the air and +0.1°C yr⁻¹ at the land surface. Our study suggests that weather conditions promoting fire emissions also tend to limit dispersion.

KEYWORDS: South America; Forest fires; Trace gases; Dispersion

1. Introduction

Greenhouse gases such as carbon dioxide are accumulating, and concentrations have more than doubled since the eighteenth century due to industrial and agricultural emissions (IPCC 2021). Over 1 Pg yr⁻¹ of smoke is released into the atmosphere through biomass burning, of which about two-thirds is from the tropics (Andreae 2019). South America has almost 0.5 billion people and an agricultural sector contribution of \$200 billion involving forest-to-farm conversion (Artaxo et al. 2002, 2013; Thornhill et al. 2018) that generates smoke plumes filled with trace gases such as carbon monoxide (CO) with a residence time of less than 2 months. Biomass burning in the southern Amazon, as in southern Africa, increases during the dry season from July to October (Garreaud and Aceituno 2001; Kingtse and Berbery 2011; Jury 2019; Yang et al. 2018). The smoke plumes extend thousands of kilometers and diminish regional air quality, impacting human health and the environment (Butt et al. 2020). Techniques to monitor fire emissions have advanced since 2000 via satellite radiometers such as MODIS and Measurements of Pollution in the Troposphere (MOPITT) and data assimilation products such as MERRA-2; hence rural air constituents and dispersion pathways can be detected. Recent studies have determined that heat-trapping trace gas emissions from tropical biomass burning are ~20 times particulate emissions (Andreae 2019) and contribute to the melting of Andean glaciers (Magalhães et al. 2019). Procopio et al. (2004) determined that wet-season-to-dry-season changes in atmospheric composition from biomass

burning increased radiative heating from 3 to 30 W m⁻² over the southern Amazon (an area of 2×10^6 km²), leading to an RCP8.5-projected +5°C rise of air temperature over the twenty-first century (Magrin et al. 2014, their Fig. 27-2).

The loss of vegetation cover compounds atmospheric heating by altering the albedo. Following a decade of moderation, deforestation increased from ~6000 to ~10 000 km² yr⁻¹ in 2019 (Pasquali 2020) as the Amazon is cleared for farming, logging and peri-urban infrastructure, thereby limiting transpiration and rainfall (Cochrane and Laurance 2008). Our work here will consider the atmospheric dispersion of smoke plumes from the southern Amazon (Penner et al. 1992; Ross et al. 1998; Li et al. 2000). We describe how seasonal weather conditions accelerate fire emissions and limit the dispersion of smoke plumes by stagnation of flow beneath a subsiding layer. In the concluding section we link the changing atmospheric composition to warming trends.

2. Data and methods

Our study covers an outer domain of 40°S–15°N, 30°–90°W and a southern Amazon index area that covers 5°–15°S, 50°–70°W, ~2.4 × 10⁶ km². This area (cf. Fig. 1d) has LaPaz/Brasilia at the lower corners and Manaus near the top center, and it lies downwind (west) of fire emissions. Concentrations of near-surface trace gases: carbon monoxide (CO), methane (CH₄), ozone (O₃), nitrogen dioxide (NO₂), and fine particulates [aerosol optical depth (AOD)] were obtained from the MOPITT, AIRS, Ozone Monitoring Instrument (OMI), and MODIS satellite radiometers and from MERRA-2 reanalysis via NASA Giovanni (Acker and Leptoukh 2007). The MOPITT radiometer detects 2.3–4.7-μm spectral bands sensitive to near-surface CO (Worden et al. 2010), and monthly means were obtained (algorithm v8). Because of its wider swath, daily CO and CH₄ data (algorithm v6) were obtained from the AIRS radiometer (Yurganov et al. 2008; Thonat et al. 2012). The AOD

FIG. 1. Annual mean map of (a) MOPITT 900-hPa CO (shaded; ppb) and 925–700-hPa wind vectors (the large arrow refers to smoke plumes from Africa). Annual mean vertical sections of MOPITT CO (shaded; ppb) and atmospheric circulation: (b) south–north axis (55°–65°W) meridional vectors and upper jet contours and (c) west–east axis (7°–13°S) zonal vectors; vertical motion is exaggerated 50-fold. (d) MODIS AOD 0.550 μm and southern Amazon index (outlined box). (e) Seasonal aerosol profiles from *CALIPSO* 0.532- μm extinction over the southern Amazon index area, with dry season shaded.

fraction was extracted at monthly and daily time scales from MODIS radiometer scattering at 0.55 μm (algorithm v6). Tropospheric NO_2 data were obtained from the OMI satellite radiometer (Bucsela et al. 2013). Table 1 lists the acronyms and details of the datasets. The methods are applied in sequence: (i) mean patterns of dispersion, (ii) characteristics of fire emissions, (iii) year-to-year and day-to-day variability, (iv) analysis of a period of high smoke emissions, and (v) climate trends. Among the air constituents, CO and AOD are more localized and best describe smoke-plume dispersion.

MERRA-2 is based on global data assimilation by NASA that provides gridded fields of atmospheric variables, aerosols, and trace gases, coupled with the land and ocean (Molod et al. 2015; Randles et al. 2017). A secondary atmospheric reanalysis used here is NCEP2 (Kanamitsu et al. 2002). The meteorological data include near-surface winds, surface air pressure, air

temperature and humidity, and derived variables such as heat and moisture fluxes and vertical motion. Supplementary data include MODIS fire emission and count density (firms.modaps.eosdis.nasa.gov/; globalfiredata.org/) based on Justice et al. (2002), and *CALIPSO* satellite aerosol profiles based on lidar extinction at 0.532–1.064 μm (Winker et al. 2007; Amiridis et al. 2015).

Monthly CO time series were formed by averaging the 900-hPa MOPITT and MERRA-2 values over the southern Amazon, 5°–15°S, 50°–70°W, in the period 2000–18, and then calculating the mean annual cycle. All-year and dry-season patterns were analyzed, and vertical sections of CO concentration and NCEP2 circulations were averaged over 55°–65°W and 7°–13°S. To understand how variations in southern Amazon CO values each dry season (July–October) are forced, field correlations were calculated with NOAA sea surface

TABLE 1. Dataset acronyms and details.

Acronym	Name	Space resolution; time resolution	Quantity
AIRS	Atmospheric Infrared Sounder, version 6	100 km; daily and monthly	CO and CH ₄ near surface
CALIPSO	Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observation, L3	~10 km at zenith; weekly overpass	Fine aerosol density, from light extinction
HYSPLIT	Hybrid Single-Particle Lagrangian Integrated Trajectory model	~10 km; within plume	Forward dispersion simulation
MERRA-2	Modern-Era Retrospective Analysis for Research and Applications with GEOS-5 air chemistry, version 5	~50 km; 3-hourly, daily, and monthly	Near-surface O ₃ , CO, and meteorological conditions
NCEP2	National Centers for Environmental Prediction, version 2, reanalysis	180 km; monthly	Atmospheric circulation
MODIS	Moderate Resolution Imaging Spectrometer, version 8, visible and infrared emissions/backscatter	~10 km; daily and monthly	Imagery, fires, and AOD
MOPITT	Measurements of Pollution in the Troposphere, version 8	100 km; monthly	CO, near surface, and multispectral
NOAA	National Oceanic and Atmospheric Administration satellite visible and infrared composites	10–100 km; daily and monthly	Vegetation, SST, and net OLR
OMI	Ozone Monitoring Instrument (<i>Aura</i> satellite) v3	25 km; twice daily	Near-surface NO ₂

temperature and vegetation fraction, and MERRA-2 sea level air pressure, 500-hPa zonal winds, and soil moisture, where 90% confidence is reached with correlation coefficient $r > |0.35|$ for a sample size of 18 years. Similarly, temporal lag correlations of July–October CO values (peaks in Fig. 3a) with Niño-3 Pacific SST and southern Amazon soil moisture and satellite vegetation were calculated from -12 to $+12$ months to understand what is driving the interannual variability.

Daily satellite concentrations of smoke-plume constituents (O₃, AOD, CO, NO₂, and CH₄) and a variety of MERRA-2 meteorological parameters averaged over the southern Amazon were extracted for the highest season on record, August–October 2007 (cf. Table 2): near-surface temperature, specific humidity, and winds; 500-hPa vertical motion and geopotential height; potential evaporation/transpiration; and surface air pressure. Daily pairwise cross correlations were calculated for the 2007 dry season to determine influences on dispersion, where 90% confidence is reached with $r > |0.50|$ for a sample size of 90 days.

For the month with highest CO concentration, September 2007 (cf. Fig. 3a), vertical sections of CALIPSO aerosol density were obtained for 2 September and 9 September 2007. HYSPLIT simulated dispersion for a continuous emission at 10°S, 55°W at 1000-m elevation in the period 15–18 September 2007, similar to Magalhães et al. (2019). HYSPLIT (Stein et al. 2015) represents the Lagrangian diffusion of pollutants within a specified period by weather data assimilation. To determine whether the smoke plume affects local climate, a brief trend analysis was calculated by linear regression of annual NOAA (no-noise, smoothed, brightness temperature: “SMT”) vegetation temperature, and NCEP2 air temperature and wind circulation 1980–2018. The slope (e.g., dT/dt) is spatially mapped over the southern Amazon region. The hypothesis is that a faster rate of warming will emerge in areas covered by smoke plumes.

We note that policies aimed at controlling emissions may affect variability or trends that are beyond the scope of research.

3. Results

a. Mean patterns: Air constituents

Figure 1 characterizes the mean trace gas and aerosol footprints in the study period 2000–18. The annual mean MOPITT

TABLE 2. Correlation of daily near-surface air constituents and meteorological conditions averaged over the southern Amazon index area for 1 Aug–31 Oct 2007; meteorological r values above 90% confidence with $N = 90$ are shown with boldface font. Air constituents are illustrated in Fig. 5a. Meteorological parameters are as follows: 500W = 500-hPa vertical motion, with positive values indicating sinking; deltaT = 850-hPa temperature minus surface temperature, with positive values indicating stable air; U850 = 850-hPa zonal wind, with negative values indicating wind from the east; V850 = 850-hPa meridional wind, with negative values indicating wind from the north; Q925 = 925-hPa specific humidity; transpir = latent heat flux, with positive values indicating upward flux; Tmin = minimum surface temperature.

CO distribution (Fig. 1a) exceeds 100 ppb over the center of South America (10°S, 60°W, 900 hPa) where winds are westward at $\sim 4 \text{ m s}^{-1}$. There is a remnant CO plume from Africa (5°N, 30°W). In the north–south section (Fig. 1b) the CO maximum below 600 hPa at 10°–15°S is drawn poleward by the subtropical jet stream (Garreaud and Aceituno 2001), and the east–west section illustrates the CO maximum spreading westward (Fig. 1c). The mean zonal circulation weakens to $\sim 1 \text{ m s}^{-1}$ on approaching the Andes Mountains, accumulating smoke plumes over Rondônia, Mato Grosso, and the Pantanal.

The aerosol footprint (AOD; Fig. 1d) is concentrated over the same southern Amazon area as CO—that is, 5°–15°S, 50°–70°W—following southwestward dispersion from eastern Brazil by anticyclonic winds. The CALIPSO extinction profile (Fig. 1e) shows a dense surface layer, low values $\sim 1 \text{ km}$ above ground, and then a prominent aerosol layer at 2 km, which tapers off above 4 km, similar to Gonzalez-Alonso et al. (2019). From the profile, we infer that buoyant smoke plumes rise into the 1000–3000-m layer during initial dispersion. The Global Fire Emission Database counts $\sim 200\,000$ fires annually within the southern Amazon area, consistent with earlier findings of Potter et al. (2002).

b. Mean patterns: Fire emissions

In Fig. 2 we characterize land temperatures and fire emissions. The MODIS daytime land surface temperature map for July–October (Fig. 2a) shows a distinct east–west axis $>40^\circ\text{C}$ on 10°S extending from 40° to 60°W (cf. Morgan et al. 2019). The satellite fire map (Fig. 2b) reveals dense concentration along the same east–west axis, upwind of the CO and AOD footprints as expected from dispersion. Its mean annual cycle averaged over the southern Amazon (Fig. 2c) shows that fire density and emissions rise suddenly in July, peak in August–September, and decline rapidly in October. Fire counts are very low from November to June because of moist soil and vegetation. Morgan et al. (2019) demonstrate a tight relationship (r^2 of 0.57–0.86) between fire counts and AOD over the southern Amazon.

c. Temporal features and annual cycle

The time series of near-surface CO and AOD over the southern Amazon is given in Fig. 3a. Sharp seasonal peaks are evident; highest monthly values came in September 2007 as a Pacific La Niña developed (NOAA 2007). The smoke constituents show insignificant downward trends ($r^2 < 0.023$) in contrast with Morgan et al. (2019). The mean annual cycle of air constituents demonstrates how the fire emissions accumulate over the southern Amazon (Fig. 3b). Values rise for CH_4 after June, peak for CO and NO_2 in September, and continue high for AOD/ O_3 into October. The air is relatively free of smoke plumes during and after the wet season. The net OLR annual cycle (Fig. 3c) reflects low values under cloudy skies (November–April) and high values in austral winter (June–August) that contribute to desiccation.

d. Interannual variability

Lag correlation of July–October 2000–18 CO values over the southern Amazon with local and regional variables is

FIG. 2. July–October mean MODIS satellite: (a) land surface temperature shaded above 24°C and (b) fire count density. (c) Mean annual cycle of fire count (number per month $\times 1000$) and emissions (Tg month^{-1}) within the southern Amazon index area ($\sim 2.4 \times 10^6 \text{ km}^2$).

FIG. 3. (a) Time series of near-surface CO concentration and AOD fraction over the southern Amazon, and case study. Also shown is the mean annual cycle of (b) near-surface air constituents (ppb) and AOD (second y axis) and (c) net OLR as a proxy for dryness (red is the mean, and yellow indicates the upper and lower quintiles).

presented in Figs. 4a–c. For Niño-3 Pacific SST, the correlations are negative (e.g., La Niña enhancement) before and during the burning season ($r < -0.4$ from -8 to $+2$ months). Thereafter, the SST correlation rises. The CO lag correlation with local soil moisture is negative during the burning season (0 lag), but neutral before to positive after. Similarly, the CO lag correlation with local vegetation is negative during the season. However, in the preceding (-9) and following ($+6$) months the vegetation is positively correlated, indicating that the fuel available for fire emissions is enhanced with respect to July–October CO concentrations. Chen et al. (2017) point out that increased biomass in the preceding and following year may contribute to a cascade of fire emissions. The narrow dip in the CO–vegetation graph (Fig. 4c) supports this idea.

Using the times series of southern Amazon CO for July–October 2000–18, it is evident from the field correlation maps (Figs. 4d–f) that cooler sea temperatures and higher pressure in the east Pacific Ocean enhance fire emissions, consistent with La Niña (Andreoli et al. 2018). 500-hPa zonal wind correlations

indicate westerlies ($+r$) over Peru and easterlies ($-r$) over Brazil: opposing flows that confine the smoke plumes. Correlation of July–October CO data with fields of satellite vegetation and soil moisture (Figs. 4g,h) show wet conditions north (10°N) and south (35°S), and dry conditions across the zone of greatest fire emissions (5° – 20°S) as expected. The temporal and spatial statistics reveal interannual climate modulation of trace gas concentrations derived from biomass burning, notably enhancement by La Niña.

e. Intraseasonal fluctuations: August–October 2007

The case of high CO concentrations during onset of Pacific La Niña from August to October 2007 provides an intraseasonal focus. Figure 5a shows the upper winds and humidity and identifies the passage of three Rossby waves in the upper westerlies and two spells of intensified easterlies. The second Rossby wave in mid-September is preceded by weak winds, while the third Rossby wave in early October is followed by a jump in humidity. Intraseasonal changes in

FIG. 4. Interannual lag correlation of southern Amazon July–October CO values with (a) Niño-3 Pacific SST, (b) local soil moisture, and (c) local vegetation fraction, from 12 months before (negative x axis) to after, with 95% confidence envelope. Also shown is the interannual correlation of July–October 2000–18 CO concentrations (peaks in Fig. 3a) onto (d) NOAA sea surface temperature, (e) MERRA-2 surface air pressure, (f) 500-hPa zonal wind (with the fire icon at the maximum), (g) soil moisture, and (h) NOAA vegetation with reversed scale. Dashed lines over the correlation shading in (d) refer to August–October 2007 SST anomalies.

dispersion can be traced to the upper “jet” and cool east Pacific SST (cf. Fig. 4d).

Daily fluctuations are evident in the time series of air constituents and weather parameters in Figs. 5b–d. There is a slow rise of trace gases and aerosols associated with smoke plumes during August, then three major AOD/NO₂ pulses in September, followed by a decline in October 2007. The smoke plumes dispersed within dry weather, sinking motions, stable lapse rates and vigorous easterly winds in August and early September 2007. Fluctuations of lapse rate and zonal wind precede peaks in pollutant concentration by a few days, associated with the abovementioned passage of midlatitude

perturbations. A final dry spell at the end of September 2007 is followed by rising motion, greater humidity, and weak winds during October 2007, conditions that tend to suppress fire emissions.

Daily pairwise cross correlations are listed in Table 2 and reveal some expected results and a few surprises. The air constituents show agreement with each other, reaching $r = 0.92$ for near-surface CO and O₃. Subsidence at 500 hPa (positive 500W) increases AOD and CH₄ (+ r) but not other constituents. Northwesterly flow (+ U and $-V$) accumulates CO and O₃ but has little effect on other constituents. The ΔT (lapse rate) shows negative association; hence unstable conditions

FIG. 5. (a) Height–time section from 5 to 15 km (500–100 hPa) of upper-wind vectors (m s^{-1}) and specific humidity (g kg^{-1}) in August–October 2007, showing passing Rossby waves (R) and easterlies (E). Daily time series (August–October 2007) over the southern Amazon area of (b) near-surface air constituents (ppb; AOD uses second y axis), (c) 925-hPa specific humidity and (inverted) 500-hPa vertical motion (below dashed line indicates sinking), and (d) (inverted) 850-hPa U wind and 850–1000-hPa temperature anomaly (positive values indicate stable air). The time axis at the bottom of the figure applies to all panels, and vertical lines enclose the dispersion simulation on 15–18 Sep. Daily correlations are listed in Table 2.

FIG. 6. August–October 2007 high-case mean (a) net OLR anomaly (W m^{-2}) and 925–700-hPa wind anomalies (m s^{-1}), (b) GRACE soil water anomaly (cm), (c) NOAA satellite vegetation anomaly, (d) MODIS fire-burn intensity shaded from yellow to orange (indicating the nocturnal fire temperature range as estimated by satellite IR), and HYSPLIT simulation point (circle), (e) OMI tropospheric NO_2 concentration (ppb), and (f) MERRA-2 O_3 concentration at 900 hPa (ppb), with the large arrow referring to smoke plumes from southern Africa.

FIG. 7. (a) September 2007 mean MOPITT CO concentration at 900 hPa (ppb). South–north slices of *CALIPSO* lidar aerosol density (b) along 57°W on 2 Sep 2007 and (c) along 60°W on 9 Sep 2007, illustrating the depth of the smoke plume (based on backscatter at 1.064 μm); HYSPLIT-simulated dispersion over 3 days from 0000 UTC 15 Sep 2007 with source at 10°S, 55°W at 1000-m elevation, showing (d) the map and (e) an west–east section (black below 3 km). (f) Smoke-plume arrival times with expanded scale. Overlaid in (d) are 200-hPa geopotential heights from 12 200 to 12 400 m, showing the upper ridge.

due to surface heating favor increased emissions/decreased dispersion. Another surprising result is that humidity and transpiration relate to greater trace gases and aerosols over the southern Amazon in the August–October 2007 period. A few caveats apply: (i) humidity affects satellite retrievals, (ii) constituent residence time alters sensitivity and response, and (iii) radiative feedback is just as likely as weather forcing.

f. Spatial analysis: August–October 2007

Figures 6a–d illustrates the anomaly patterns during this case, based on the departure from the 2000–18 mean. The net OLR shows an anomalous warm dry area over much of Brazil under easterly flow, while the GRACE satellite soil moisture has two dry areas: 5°–10°S near the Amazon and a northwest

axis at 20°–25°S. NOAA satellite vegetation anomalies are negative (dry) over Brazil, Peruvian lowlands, and the Parana River valley (22°S, 57°W); in contrast with weak values near the Amazon River. The west negative/east positive pattern across the southern Andes relates to orographic clouds on windward slopes. The fire density map follows the net OLR pattern with burning across the area 5°–25°S, 45°–65°W. MODIS fire statistics indicate a mean duration of 5–10 days and average individual size of 10–20 km². The August–October 2007 mean OMI tropospheric NO₂ and MERRA-2 900-hPa O₃ maps (Figs. 6e,f) show different stages of smoke-plume dispersion. NO₂ concentrations are greatest over the fires of Brazil, whereas the near-surface ozone spreads southwest after aging and anticyclonic transport. Along with the local smoke

FIG. 8. Maps for 14 Sep 2007 of (a) a MODIS visible image of the smoke plume with topographic details and (b) MERRA-2 near-surface 850-hPa temperature (shaded) and upper 200-hPa winds (vectors). Also shown are mean September 2007 conditions: (c) south–north section 55°–65°W of MOPITT CO (ppb) and NCEP2 meridional circulation vectors and upper-jet contours and (d) profiles of MERRA-2 vertical motion (red, labeled omega; Pa s^{-1}) and AIRS CH4 concentration (ppb; green). Positive omega refers to sinking motions (as indicated by the arrows).

plume, some of the secondary O_3 arrives from southern Africa (18°S, 30°W) and passes over the Andes to the west coast.

High concentrations of CO are evident across the center of South America in September 2007 (Fig. 7a). The CALIPSO sections (Figs. 7b,c) illustrate the buildup of smoke plumes from 2 to 9 September 2007: initially 11°–14°S, spreading to 5°–23°S. The lidar sections reveal that smoke-plume aerosols are vertically dense from surface to 4 km; the top of the boundary layer is sharply limited by subsidence. The HYSPLIT simulated dispersion from a continuous emission at 10°S, 55°W at 1000-m elevation in the period 15–18 September 2007 is westward (Fig. 7d), but after spreading by 10° latitude and 20° longitude, the plume is blocked by the Andes Mountains and accumulates over the lowlands of Bolivia. Of interest is the upper geopotential pattern driving a fast jet stream along 30°S latitude and an anticyclonic ridge downstream. The HYSPLIT vertical dispersion (Fig. 7e) slightly exceeds the depth observed by CALIPSO: 5 versus 4 km. Plume arrival times (Fig. 7f) quantify westward expansion on 15–16 September 2007, followed by

a slowing over the foothills of the Andes on 17 September. The 200-hPa flow imparts anticyclonic vorticity of $\sim 10^{-4} \text{ s}^{-1}$ and sinking motions that prevent upward diffusion. Hence there is a stagnation of flow that accumulates pollutants beneath a subsiding layer.

Dense smoke plumes are evident in the MODIS visible image of 14 September 2007 (Fig. 8a) between fire emissions at 55°W and the Andes at 65°W. Upper winds and near-surface temperatures on 14 September 2007 (Fig. 8b) reflect the jet stream at 30°S curving equatorward over a warm circular area where the smoke plumes are confined to 15°S. Cuiaba, Brazil, is centrally located (15°S, 56°W), and its radiosonde profile on 14 September 2007 (Table 3) lists weak northerly winds below 700 hPa. A hot dry layer is present from 975 to 925 hPa with temperature $T > 30^\circ\text{C}$ and dewpoint $T_d < 5^\circ\text{C}$. Above 600 hPa, the $T - T_d$ difference exceeds 30°C , indicative of extraordinary subsidence during this episode. Southeasterly winds above 600 hPa disperse some of the fire emissions toward Bolivia.

TABLE 3. Cuiaba radiosonde profile at 0000 UTC 14 Sep 2007. Large differences between temperature and dewpoint within the boundary layer indicate subsiding air. For wind speed, 1 kt = 0.51 m s⁻¹.

988	182	33.0	10.0	350	4

The mean CO concentration and meridional circulation during September 2007 (Fig. 8c) reflects sinking motions over southern Amazon fires and poleward transport. Greatest CO values are found in the 900–600-hPa layer from 10° to 26°S, adjacent to the upper jet. The MERRA-2 vertical motion profile averaged over the southern Amazon in September 2007 (Fig. 8d) reveals a deep layer of subsidence from 700 to 300 hPa, which confines high CH₄ concentrations in the layer beneath.

g. Climate trends

Linear trends of NCEP2 air temperature and the meridional circulation in the period 1980–2018 are given in Fig. 9a and show a warming rate of +0.03°C yr⁻¹ that tilts poleward with height, consistent with smoke-plume constituents, circulation trends and Magrin et al. (2014) projections. Trace gases from biomass burning correspond with faster atmospheric warming, and areas of dense fires coincide with faster surface warming (+0.1°C yr⁻¹; Fig. 9b). This points to human-altered landscapes and associated moist energy imbalance (Cochrane and Laurance 2008). As listed in Table 2, minimum temperatures tend to rise under higher CO and O₃ concentrations ($r = 0.81$), suggesting that smoke-plume constituents absorb nocturnal radiation. There are two unexpected results: (i) a high rate of vegetation warming over the Andes Mountains and Argentina and (ii) a near-zero trend in the equatorial zone. Brando et al. (2020) provide an analysis of climate trends and projections, and they conclude that locally faster warming of the air and land will contribute to forest flammability, smoke emissions, and drought.

4. Conclusions

The atmospheric dispersion of smoke plumes over South America has been analyzed via trace gas and aerosol “footprints” seen by satellites and air chemistry reanalysis. Carbon

monoxide concentrations and AOD over and west of fire emissions from the area 5°–15°S, 50°–70°W double in value from the wet season to the dry season and assume a circular shape (cf. Figs. 1a, 2a, 7a). Correlation of CO values onto fields of SST and air pressure show a cool eastern Pacific Ocean overlain with high pressure. Opposing midlevel winds accumulate trace gases (cf. Fig. 4c) while a drier surface stimulates fire emissions (cf. Figs. 4d,e), for example in September 2007. Low-level winds transport smoke plumes from eastern Brazil toward the foothills of the Andes, where they tend to stagnate and recirculate southward. Anticyclonic ridging of the jet stream imparts sinking motions that confine the smoke plumes below 4 km.

Land and air temperatures appear to be rising faster in burned zones and in smoke plumes with high AOD, CO, NO₂ concentration (cf. Figs. 1b, 9a). Particulate scattering can oppose trace gas absorption of radiation (Li et al. 2000; Jury and Whitehall 2010; Magrin et al. 2014). Palacios et al. (2020) measured aerosol size distributions in the southern Amazon and found peaks of 0.15 and 5.0 μm that contributed to surface cooling. Procopio et al. (2004) quantified the radiative impacts of smoke plumes and found a net flux of +30 W m⁻² in the dry season, within aged fire emissions dominated by CO₂ (Levine 2003). Here the collocation of smoke-plume constituents, land surface warming and rising air temperatures suggest that heat-trapping trace gases overwhelm the scattering effect of coarse aerosols, seasonal wet deposition, and feedbacks (Morgan et al. 2019) and drive net radiative absorption.

Most fires are initiated by forest to farmland conversion to feed the appetite of a growing population. Land management advice across South America is helping to level off trace gas emissions, yet respiratory health impacts are ongoing (Butt et al. 2020). Local warming rates of +0.03°C yr⁻¹ in the air and +0.1°C yr⁻¹ at the land surface (Figs. 9a,b) rank in the top 1% globally.

FIG. 9. Linear trend over 1980–2018 of annual (a) NCEP2 air temperature (shading; $^{\circ}\text{C yr}^{-1}$) and meridional circulation (vectors; $\text{m s}^{-1}/\text{yr}$) on a south–north slice averaged over 55°–65°W and (b) SMT. Burned areas and the southern Andes show warming trends $> +0.1^{\circ}\text{C yr}^{-1}$. The fire icon in (a) represents the latitude of maximum fire density.

Our study suggests that weather conditions promoting fire emissions also limit the dispersion via stagnation of flow beneath a subsiding layer. Smoke plumes blanketed many cities surrounding the southern Amazon in 2019 (Fig. 10), prompting widespread concern and calls to limit biomass burning deforestation.

Acknowledgments. Satellite and reanalysis air chemistry data were obtained from NASA–Giovanni. Atmospheric data were analyzed via the University of Hawai‘i APDRC, KNMI Climate Explorer, and IRI Climate Library; the HYSPLIT-simulated dispersion was conducted in NOAA Ready-ARL. A data spreadsheet is available on request.
