

ASSESSING AND UNDERSTANDING THE IMPACT OF STRATOSPHERIC DYNAMICS AND VARIABILITY ON THE EARTH SYSTEM

BY EDWIN P. GERBER, AMY BUTLER, NATALIA CALVO, ANDREW CHARLTON-PEREZ, MARCO GIORGETTA, ELISA MANZINI, JUDITH PERLWITZ, LORENZO M. POLVANI, FABRIZIO SASSI, ADAM A. SCAIFE, TIFFANY A. SHAW, SEOK-WOO SON, AND SHINGO WATANABE

New modeling efforts will provide unprecedented opportunities to harness our knowledge of the stratosphere to improve weather and climate prediction.

Observational and modeling studies over the past two decades have fundamentally changed our understanding of the stratosphere's role in surface weather and climate. Interactions between the stratosphere and other components of the Earth system, from the troposphere to the deep ocean, possibly even the ice sheets of Greenland and Antarctica,

reveal coupling across a wide range of spatial and temporal scales. In response to these advances, operational forecast, seasonal prediction, and coupled climate models are "raising their lids," adding model layers, incorporating more stratospheric processes, and assimilating data higher into the stratosphere than ever before.

The Modelling the Dynamics and Variability of the Stratosphere-Troposphere System (DynVar) activity of the World Climate Research Programme's (WCRP) Stratospheric Processes and their Role in Climate (SPARC) project is a multidisciplinary research forum focused on the impact of stratospheric dynamics and variability. In this article, we review recent results connecting the stratosphere to surface weather and climate, and explore key open questions facing the research community. Following a recent workshop (Manzini et al. 2011), DynVar is coordinating a new effort to address these questions with the aid of two emerging multimodel datasets. The first is part of the Coupled Model Intercomparison Project phase 5 (CMIP5) where, for the first time, several climate prediction centers will seek to accurately represent the stratosphere in coupled model integrations. A list of participating models is shown in Table 1. The second, the Stratosphere Resolving Historical Forecast Project (Strat-HFP), is a multimodel set of seasonal hindcasts, organized to elucidate the role of the stratosphere on intraseasonal time scales. The Strat-HFP is a subproject of WCRP's Climate Variability and Predictability (CLIVAR) effort to improve seasonal to interannual prediction, and further information is available on their website (www.wcrp-climate.org/wgsip/chfp/stratHFP.shtml). These new datasets will offer unrivaled opportunities to explore the role of the stratosphere in the Earth system, and they may allow us to improve our ability to forecast future weather and climate, on time scales from just a few days to centuries.

THE STRATOSPHERIC ROLE IN WEATHER AND CLIMATE.

Exploration of the stratosphere began in the second half of the nineteenth century, when technological advances first freed scientists or, perhaps more importantly, their instruments from the ground. The lapse rate of the free troposphere, approximately 7 K km^{-1} , had been established from mountain-based measurements in the eighteenth century; Hermann von Helmholtz (among others) speculated that if this lapse rate continued to higher altitudes, then the atmosphere would reach absolute zero near 30 km. Daring hot air balloon ascents revealed a reduction of the lapse rate above 12 km, a hint of what we now know to be the tropopause, but the risky ascents also cost the lives of aspiring high-altitude meteorologists.¹ It required unmanned balloon measurements, precursors of the modern radiosonde,

by Teisserenc de Bort (1902) and Assmann (1902) to safely and systematically illuminate the structure of the upper atmosphere. They revealed a stably stratified expanse of air where temperature actually increases with height, as illustrated with modern data in Fig. 1, above the unsettled motion below, inspiring Teisserenc de Bort to separate the turbulent *troposphere* ("the sphere of change," from the Greek

FIG. 1. Sample vertical temperature profile of the atmosphere, based on the Jan zonal-mean temperature at 40°N from the Committee on Space Research (COSPAR) International Reference Atmosphere 1986 model (CIRA-86). At the time of its discovery, observations were reliable only up to 15 km, and the "stratosphere" was taken to include everything above the tropopause. The modern stratosphere is bounded by the stratopause, above which temperatures begin to decline with height. Recall that the mass of the atmosphere is proportional to pressure; the stratosphere contains about 10%–20% of the total mass of the atmosphere, and everything above the stratopause, just 0.1%.

¹ Please see Hoinka (1997) and Labitzke and Van Loon (1999) for a more detailed account of the early history of upper-atmosphere exploration.

tropos, to turn or whirl) from the laminar *stratosphere* above (literally “the sphere of layers,” from the Latin *stratus*, “spread out”).

Pioneering work by Scherhag (1952), however, showed that this seemingly stable part of the atmosphere is also susceptible to violent change, with wind and temperature swings that rival those experienced in the most powerful fronts at the surface. Concurrently, Brewer (1949) and Dobson (1956) revealed that the stratosphere actively circulates from the equator to the poles, a meridional overturning now known as the Brewer–Dobson circulation. Key advances in stratospheric dynamics in the 1960s and 1970s linked stratospheric variability to tropospheric phenomena. Direct interactions are primarily at the extremes of the spatial spectrum, involving planetary-scale waves and small-scale gravity waves, but notably not synoptic waves (e.g. Charney and Drazin 1961). However, conventional wisdom maintained that interactions were primarily one way—the stratosphere passively responding to forcing from the more massive troposphere below. It required advances in observational analysis and modeling capability in the 1980s and 1990s to establish genuinely two-way interactions between the stratosphere and world below, setting the stage for the recent explosion of research on the role of the stratosphere in the Earth system.

Short-range weather prediction. An early numerical study by Boville and Baumhefner (1990) explored the impact of the stratosphere on tropospheric predictability, finding that tropospheric error growth rates increased when the stratosphere of their model was degraded. The errors, however, were relatively small until about 20 days, and thus easily overwhelmed by uncertainty in the initial conditions. Subsequent improvements in numerical weather prediction (NWP) skill have now made it possible to identify the impact of stratospheric perturbations on shorter time scales. Charlton et al. (2004) show that tropospheric forecast skill declines significantly when the initial conditions in the stratosphere are intentionally misspecified, highlighting the importance of the stratospheric state for tropospheric forecasts. In a complementary study, Jung and Barkmeijer (2006) find that forcing perturbations applied only in the stratosphere can impact the troposphere in just a few days, demonstrating the potential for model error in the stratosphere to corrupt a surface forecast.

A number of NWP centers now include a better representation of the stratosphere to improve short-range forecasts, as illustrated in Fig. 2. The improvement stems in part from the ability to assimilate data from satellite channels that project into the troposphere but extend significantly into the stratosphere. These broad channels cannot be effectively incorporated without a representation of the physics of the middle atmosphere. Clarifying the extent to which a well-resolved stratosphere improves tropospheric forecasts, over and above this initial condition effect, is an active field of research.

The difficulty of raising the model top in NWP systems stems in part from computational constraints associated with the stratospheric circulation; not only must one represent additional model layers but high stratospheric wind velocities (which can exceed 180 m s⁻¹, or 350 kt) may require a reduced time step. To address these limitations, more sophisticated numerical treatment of the stratosphere, such as upper-boundary nesting (McTaggart-Cowan et al. 2011), is being developed to allow models to more efficiently represent stratospheric conditions but still capture the predictive skill.

FIG. 2. Impact of stratospheric resolution and data assimilation on surface weather forecast skill. Plots compare the 1,000-hPa geopotential height anomaly correlation, averaged over 5-day forecasts made between Jul and Sep 2010, with two versions of the Navy Operational Global Atmospheric Prediction System (NOGAPS). Curves reveal an improvement in forecast skill in a version of the model with enhanced stratospheric representation (red), as compared to the operational model (blue) (courtesy Dr. Ben Ruston).

Intraseasonal predictability. The impact of the stratosphere on tropospheric forecast skill increases on intermediate time scales, from about a week to a season, as highlighted by a 2010 National Academy of Science study focused on improving seasonal forecasts (National Research Council 2010). The potential for extended predictability stems in part from the slow radiative relaxation rates of the lower stratosphere (Newman and Rosenfield 1997); perturbations in this region are slow to recover, and so they can provide extended memory to the atmospheric circulation on monthly time scales (Baldwin et al. 2003). The potential for predictability, however, can only be realized during seasons when the stratosphere is actively coupled with the troposphere below: winter in the Northern Hemisphere and late spring in the Southern Hemisphere.

Radiative cooling during the polar night leads to a powerful westerly jet in the stratosphere. This “polar vortex,” however, can be destroyed by bursts of planetary wave activity from the troposphere in just a matter of days (Matsuno 1971). Associated with the weakening of the winds is a dramatic warming of the polar stratosphere, locally up to 80 K, so that these events are known as stratospheric sudden warmings (SSWs) (e.g., Scherhag 1952; Labitzke 1972). SSWs occur about every other year in the Northern Hemisphere, but they have been observed only once in the Southern Hemisphere (in September 2002), where planetary wave forcing is weaker. In the Southern Hemisphere, the variability of the polar vortex is highest in November, when winter westerlies transition to summer easterlies.

Baldwin and Dunkerton (2001) demonstrate that these stratospheric anomalies propagate downward into the troposphere in approximately one week, and that they can impact the tropospheric circulation for up to two months. The downward signal from the stratosphere to the troposphere is well characterized by the “annular mode,” the dominant mode of intraseasonal variability in the extratropical atmosphere (Thompson and Wallace 1998). In the

upper atmosphere, the annular mode tracks the intensity of the polar vortex, where a positive index implies a strong vortex, while in the troposphere it characterizes the meridional position of the midlatitude jet, where a positive index implies a poleward shift of the jet. Composites formed with the annular mode index, computed separately at each height, show the downward impact of SSWs in Fig. 3. We show the response in both reanalyses and models of varying complexity to highlight the robustness of the phenomenon (see the sidebar for more information).

The negative index of the tropospheric annular mode (i.e., an equatorward shift of the midlatitude jet) following an SSW implies colder weather and more snow in the northeastern United States and northern Europe (Thompson and Wallace 2001). Christiansen

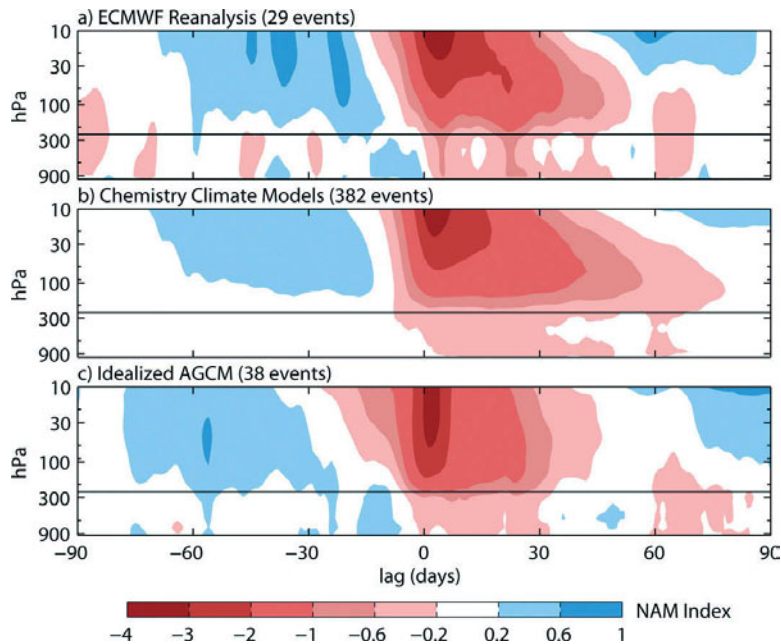

FIG. 3. Impact of the stratospheric variability on the troposphere on intraseasonal time scales. Following Baldwin and Dunkerton (2001), composites of the northern annular mode index as a function of height are made around SSW events. Negative index in the stratosphere characterizes a weakening of the stratospheric vortex, which precedes a shift toward a negative index at the surface, characterizing an equatorward shift of the tropospheric jet stream. (a) Based on the 40-yr European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis (ERA-40) and ECMWF Interim Re-Analysis (ERA-Interim). (b) Multimodel composite based on 11 CCM simulations of the twentieth century; a larger sample size smooths out the impact of tropospheric variability. (c) Based on an idealized atmospheric GCM [similar to that in Gerber and Polvani (2009)], suggesting that the mechanism behind the coupling lies in the large-scale dynamics. For these composites, SSWs are defined as instances when the stratospheric index drops below -3 standard deviations at 10 hPa. Thin black lines mark the approximate location of the extratropical tropopause.

(2005) isolates this stratospheric impact on surface weather with a statistical forecast model, Kuroda (2008) and Mukougawa et al. (2009) in NWP models, and Kolstad et al. (2010) in reanalyses and coupled climate models. Similar perturbations to tropospheric weather, but of opposite sign, are observed when the stratospheric vortex is abnormally strong, so-called polar intensification events (Limpasuvan et al. 2005). While stratospheric events offer the opportunity for extended predictability once they occur, they can be difficult to forecast far in advance, as they are initiated by tropospheric planetary waves (e.g., Polvani and Waugh 2004; Gerber et al. 2009). Cohen et al. (2007), however, suggest that early snowfall over Eurasia can amplify the planetary wave pattern in the troposphere, increasing the likelihood of a disturbed vortex in midwinter. The final, springtime warming of the polar vortex also offers the potential for improved tropospheric forecasts (Black et al. 2006). Focusing on the Southern Hemisphere, Roff et al. (2011) demonstrate that extended forecasts during austral spring can be enhanced by increasing the resolution of the stratosphere.

In addition to the zonal coupling between the polar vortex and jet stream, Perlwitz and Harnik

(2003) show evidence of direct coupling between planetary waves in the stratosphere and the troposphere. While a weaker polar vortex is associated with the breaking of planetary waves, a stronger vortex is associated with the reflection of planetary waves, leading to correlation between tropospheric and stratospheric planetary wave structures on weekly time scales. There is evidence that climate change, particularly ozone loss in the Southern Hemisphere, has modulated this intraseasonal coupling in recent decades (Shaw et al. 2011).

Interannual predictability. The natural variability of the Earth system on interannual time scales is dominated by coupled atmosphere–ocean modes—in particular, El Niño–Southern Oscillation (ENSO). The stratosphere appears to play an important role in transmitting the tropical ENSO signal to the midlatitudes (e.g., Bell et al. 2009). Extratropical upward wave propagation intensifies during warm ENSO events in boreal winter, modulating the meridional overturning circulation of the stratosphere and the stratospheric polar vortex (Garcia-Herrera et al. 2006). The vortex anomalies then propagate downward, affecting the midlatitudes in the troposphere (Cagnazzo and Manzini 2009; Ineson and Scaife 2009). The weakened polar vortex during El Niño winters tends to cause colder, snowier winters in Europe. Brönnimann et al. (2004), for instance, relate the extreme cold winters of 1940–42 to the stratospheric variability driven by El Niño. More recent work has explored the potential for coupling between the stratosphere and ocean apart from ENSO, connecting decadal variations in the Atlantic with the variability of the boreal stratospheric vortex (Schimanke et al. 2011).

The stratospheric circulation itself explicitly carries memory on interannual time scales in the quasi-biennial oscillation (QBO), an oscillation of easterly and westerly jets in the tropical stratosphere with a period of approximately 28 months. There is evidence of QBO influence at the surface (e.g., Coughlin and Tung 2001; Thompson et al. 2002; Crooks and Gray 2005), and recent studies show evidence for increased interannual predictability from the QBO (Boer and Hamilton 2008; Marshall and Scaife 2009). The mechanism may involve the stratospheric polar vortex, as QBO winds modulate the upward propagation of waves in the extratropics (Holton and Tan 1980; Calvo et al. 2009).

The stratosphere also plays an important role in determining the climate response to volcanic and solar forcing. Scattering of incoming solar radiation by stratospheric aerosols after volcanic eruptions leads

MODELING THE MIDDLE ATMOSPHERE: CHEMISTRY–CLIMATE MODELS

Middle atmospheric modeling with general circulation models (GCMs) has a long history (e.g., Fels et al. 1980; Boville 1984). To date, the most sophisticated representation of the stratosphere–troposphere system is found in Chemistry–Climate models (CCMs). A CCM is an atmospheric model designed to predict changes in stratospheric ozone. It is run at comparable horizontal resolution to the atmospheric component of a coupled climate model, but with finer vertical resolution in the middle atmosphere and a model lid generally above the stratopause. Most importantly, CCMs simulate the processes involved in stratospheric ozone chemistry, including the heterogeneous reactions on polar stratospheric clouds responsible for the Antarctic ozone hole. Thus, scenario forcings must include relevant ozone-depleting substances, in addition to greenhouse gases. Given the computation resources needed to simulate stratospheric chemistry, in addition to more sophisticated gravity wave and radiative transfer parameterizations appropriate for the middle atmosphere, to date most CCMs have been run with prescribed sea surface temperatures, often taken from reanalyses or coupled climate integrations. The first international modeling intercomparison of the troposphere–middle atmosphere system was reported by Pawson et al. (2000). For more information on the latest generation of CCMs, see Eyring et al. (2010), summarizing the second CCM Validation Activity (CCMVal2) of SPARC.

to surface cooling, up to 0.1–0.2 K in the global mean (Robock and Mao 1995). While tropospheric aerosols are washed out of the atmosphere relatively quickly by the hydrological cycle, stratospheric aerosols last up to two years, giving persistence to the volcanic signal. The Brewer–Dobson circulation plays a role in the global response, lifting aerosols upward in the tropics and spreading them across the extratropics of both hemispheres. For this reason, tropical volcanic eruptions have much more global, long-lasting impacts on climate than comparable eruptions in the high latitudes. While sulfate aerosols cool the surface by scattering incoming radiation, they warm the stratosphere by absorbing in the infrared (Angell 1997). This stratospheric temperature signal could lead to potentially unexpected changes in surface temperature on regional scales; Europe appears to experience warmer winters following major volcanic eruptions because warming in the tropical lower stratosphere may lead to a stronger, colder polar vortex, shifting the tropospheric jet stream poleward (Robock and Mao 1992). Confirmation of this effect in models, however, has proved difficult (e.g., Marshall et al. 2009).

The net radiative perturbation associated with the 11-yr solar cycle is relatively small, approximately 0.2 W m^{-2} averaged over the Earth's surface, less than 0.1% of the total incoming solar radiation. The relative variance is considerably larger in the UV range of the spectrum, and thus leads to more substantial perturbations in stratospheric ozone and temperature (e.g., Haigh 1996; Gray et al. 2010). Changes in stratospheric temperature gradients could affect the wave coupling between the troposphere and stratosphere, potentially impacting regional surface climate (e.g., Kodera and Kuroda 2002). Thus, the primary impact of solar variability on the troposphere may be on the regional scale, related to solar-induced changes in the Brewer–Dobson circulation and the lowermost tropical stratosphere (Matthes et al. 2006). Untangling the 11-yr solar cycle signal from that of ENSO or the QBO, however, is not a trivial task, both in the tropics (e.g., Marsh and Garcia 2007) and the extratropics (e.g., Camp and Tung 2007). More recent analysis of perturbations associated with the solar cycle by Lean and Rind (2008) and new satellite-based measurements of the current cycle by Haigh et al. (2010) have in fact questioned our current understanding of solar impacts.

Anthropogenic climate change. On decadal time scales and longer, the impact of anthropogenic forcing on the stratosphere becomes significant. The

most notable example is the destruction of stratospheric ozone by chlorofluorocarbons and other halogenated compounds. The Antarctic ozone hole, a near-complete destruction of ozone between 12 and 25 km, forms each austral spring when sunlight first breaks on activated halogen reservoirs built up over the polar night (Farman et al. 1985; Solomon 1999). The depletion of ozone cools the lower stratosphere by up to $\sim 10 \text{ K}$, strengthening the westerly winds in the polar vortex and delaying the seasonal transition from winter westerlies to summer easterlies (Thompson and Solomon 2002).

This perturbation to the lower stratosphere is, in turn, associated with a poleward shift of the tropospheric jet stream and storm track from December to February. Chemistry–Climate Models (CCMs) run with and without ozone-depleting substances have directly attributed the observed stratospheric cooling, and thus the corresponding changes in the tropospheric circulation, to stratospheric ozone loss (e.g., Perlwitz et al. 2008). Greenhouse gas (GHG)-induced warming of the troposphere also forces a poleward shift of the tropospheric jet stream (e.g., Kushner et al. 2001; Yin 2005), so that over the past four decades, both ozone loss and GHG increases have been driving the poleward shift of the Southern Hemisphere storm track. This raises two questions: first, over the observed record, how much of Southern Hemisphere climate change should be attributed to ozone loss versus GHG increases? and second, what should be anticipated in the future, when the effects of the expected ozone hole recovery oppose those due to GHG increases?

These questions are partially answered by an unintentional experiment conducted by coupled climate model simulations prepared for the Intergovernmental Panel on Climate Change's Fourth Assessment Report (IPCC AR4). As explored by Son et al. (2008), stratospheric ozone was not mandated in the CMIP3, leaving each modeling group to choose a strategy. Roughly half of the models included ozone loss and recovery in their integrations, while the other half kept climatological ozone fixed. As shown in Fig. 4, models with steady ozone exhibit a poleward shift of the jet in both the twentieth and twenty-first centuries, while models with time-varying ozone exhibit *stronger* jet stream trends in the twentieth century, when ozone and GHG changes work together, but *exhibit almost no trend* at all in the twenty-first century, as the two forcings oppose one another, effectively canceling each other out. Multimodel analyses (e.g., Son et al. 2008; Fogt et al. 2009) and attribution studies with individual models (Arblaster

and Meehl 2006; Perlwitz et al. 2008; Polvani et al. 2011; McLandress et al. 2011) all suggest that ozone-induced cooling of the polar stratosphere has dominated Southern Hemisphere climate change in austral spring and summer over the last few decades. It is also clear that ozone forcing will play an important role in future climate change, and it is supposed to be

included in all coupled climate models in the CMIP5 experiments.

The shift in the austral jet stream has had substantial implications on the hydrological cycle of the Southern Hemisphere, deep into the subtropics (Kang et al. 2011). Its effect on global climate may be magnified through coupling with the Southern Ocean, the primary sink of atmospheric CO₂ in the oceanic carbon cycle. Studies have suggested that the increased ventilation of carbon-rich deep water driven by the poleward shift of the austral jet stream has

FIG. 4. Impact of stratospheric ozone loss and recovery on recent and projected climate change in the Southern Hemisphere. Shading shows trends in December–February (DJF) zonal-mean zonal wind ($\text{m s}^{-1} \text{decade}^{-1}$) during (a)–(d) 1960–99, the period of ozone loss; and (f)–(h) 2000–79, the period of expected ozone recovery. Black contours denote the climatological jet from 1960 to 1999. (a) Trends based on ERA-40: the positive (negative) trends on the poleward (equatorward) flanks of the mean jet characterize a poleward shift of the jet. As re-analyses in the Southern Hemisphere are less reliable in the presatellite era, we also show trends (e) from 1979 to 1999 to confirm their structure. Trends are stronger over this shorter period, which captures the peak changes in ozone depletion, but we focus on the full period, 1960–99, in the models as the larger sampling reduces statistical uncertainty. (b),(f) Results for CMIP3 models forced with fixed ozone; here, the trend is underestimated over the past four decades, but it continues with comparable strength in the future. (c),(g) Results from CMIP3 models that were forced with time-varying ozone; these models better capture observed trends and suggest that stratospheric ozone and tropospheric GHG forcings will effectively cancel out over the next 80 years. (d),(h) Based on the second CCM Validation Activity models (CCMVal2) with interactive ozone chemistry. Similarities between the four bottom panels suggest that CMIP3 models forced with specified ozone appear to capture the essential impact of stratospheric ozone trends.

both weakened the Southern Ocean carbon sink (e.g., Lovenduski et al. 2008) and accelerated ocean acidification (Lenton et al. 2009). A note of caution may be in order, as the relatively coarse resolution of the ocean simulated in coupled models may be missing feedbacks within the oceanic circulation that would make it less sensitive to atmospheric forcing (e.g., Böning et al. 2008). Changes in the coupled atmosphere–ocean circulation may also affect sea ice trends in the Southern Ocean (Turner et al. 2009), but a lack of agreement between models suggests the need for further study (Sigmond and Fyfe 2010).

There is not a comparable ozone hole in the Northern Hemisphere because the boreal winter vortex is warmer, which limits the formation of polar stratospheric clouds crucial to the chemistry of rapid ozone loss. Model simulations of twentieth-century and twenty-first-century circulation trends in the Northern Hemisphere, however, indicate an important role of the stratosphere in the coupled stratosphere–troposphere response to anthropogenic forcing. Most models are unable to capture the observed poleward trend of the Northern Hemisphere tropospheric storm track from the 1970s to the mid-1990s. Prescribing trends in the lower stratosphere makes it possible to capture the tropospheric trends without affecting the global-mean warming signal (Scaife et al. 2005), and improved stratospheric variability in coupled climate models has been shown to improve the simulation of twentieth-century climate (Dall’Amico et al. 2010). Sigmond et al. (2008) find that the response of the tropospheric storm track to a doubling of CO₂ can depend critically on subtle changes in the stratospheric mean state influenced by the parameterization of orographic gravity waves. More generally, Scaife et al. (2011) show that stratosphere–tropospheric interactions can influence twenty-first-century climate change predictions for the Atlantic storm track, with substantial impacts on the hydrological cycle over Europe.

OPEN QUESTIONS AND NEW FRONTIERS.

While advances in our understanding of stratosphere–troposphere interactions have raised the possibility of improving weather and climate prediction, there remain important questions in how to utilize these gains. From a conceptual and practical standpoint, it is not entirely clear what is necessary to capture a “well represented” stratosphere for the purposes of climate or weather prediction. Adding more model layers and stratospheric processes (such as nonorographic gravity waves, stratospheric chemistry, and microphysics) comes with significant computational

expense. Hence, the relevant question is, how much of the stratosphere needs to be represented in a model to capture its influence on the troposphere? From a scientific perspective, a better understanding of the mechanisms coupling the stratosphere to other components of the Earth system is also needed.

Mechanisms. A key coupling between the stratosphere and troposphere is the link between the strength of the stratospheric polar vortex and the position of the troposphere midlatitude jet and storm track, as illustrated on intraseasonal and decadal time scales in Figs. 3 and 4, respectively. Several mechanisms have been proposed, but it has been difficult to isolate the key pathway(s). One view focuses on the balanced response of the troposphere to stratospheric potential vorticity anomalies and wave-driven changes in the meridional circulation (e.g., Hartley et al. 1998; Thompson et al. 2006). A second body of research suggests that the tropospheric response involves changes in synoptic eddies (e.g., Kushner and Polvani 2004; Song and Robinson 2004). Mechanisms based on linear theory highlight the influence of lower-stratospheric conditions on the refraction of synoptic waves (Limpasuvan and Hartmann 2000; Simpson et al. 2009) and the potential for constructive and destructive influence of climatological and forced planetary waves (Fletcher and Kushner 2011). Lower-stratospheric wind and temperature perturbations may also directly affect baroclinic instability (e.g., Rivière 2011) and impact tropospheric wave breaking (Wittman et al. 2004; Chen and Held 2007; Kunz et al. 2009). The range of possible mechanisms suggests a need for greater connection between our theoretical understanding with observations and model simulations.

Missing physical and chemical processes. Uncertainty also lies in stratospheric processes that can only be parameterized at a current model resolution. Alexander et al. (2010) highlight concerns about the treatment of unresolved gravity waves. Most gravity wave parameterizations are highly idealized, in part for a lack of observational constraints, but also to maintain their computational efficiency. Simplification of gravity wave sources limits their potential to evolve in a changing climate. The role of interactive ozone chemistry is also a partially open question. As seen in Fig. 4, CMIP3 models driven with prescribed ozone loss and recovery capture the first-order effect of ozone on the troposphere, but Waugh et al. (2009b) caution that they may underestimate the response when compared to a fully interactive

simulation. Last, the transport of water vapor into the stratosphere, which plays a key role in both chemistry and radiation (Solomon et al. 2010), appears sensitive to microphysical processes in the tropical tropopause layer (e.g., Fueglistaler et al. 2009). Gettelmen et al. (2010) find that the representation of tropical tropopause temperatures and water vapor varies considerably in current Chemistry–Climate Models.

Stratospheric climate change. Understanding these unresolved processes may be important for predicting the effects of anthropogenic climate forcing on the stratosphere itself, which is necessary for capturing the impact of the stratosphere on the world below. For example, integrations with Chemistry–Climate Models suggest that the Brewer–Dobson circulation is strengthening and will continue to do so throughout the twenty-first century (e.g., Butchart and Scaife 2001; Butchart et al. 2010). An analysis of stratospheric tracers over the last three decades, however, suggests a weakening of mass transport (Engel et al. 2009), although model trends cannot be ruled out because of substantial uncertainty in the observations (e.g., Garcia et al. 2011). The model trends are consistent with a rise of wave breaking associated with anthropogenic forcing (Calvo and Garcia 2009; Shepherd and McLandress 2011), while Bönisch et al. (2011) argue that the differences in observations and models could be evidence of structural changes in the meridional overturning. If the Brewer–Dobson circulation does increase, leading to greater mass transport from the tropics to the extratropics, then tropical ozone may never recover to preindustrial levels, while extratropical ozone will become larger than ever before (Shepherd 2008; Waugh et al. 2009a). Changing the horizontal gradient of ozone can have important dynamical feedbacks in the stratosphere and troposphere. Changes in the Brewer–Dobson circulation may also be linked to changes in tropical cyclone activity in the North Atlantic. Recent trends in the potential intensity, an indicator of tropical cyclone activity, appear to depend on the temperature trends in the outflow region of the upper troposphere and lower stratosphere, which are sensitive to the stratospheric circulation (Emanuel 2010).

Tropospheric sensitivity. Once stratospheric trends are established, we must also narrow the uncertainty in the tropospheric circulation response to stratospheric perturbations. Son et al. (2010) compare the shift of the austral jet stream in response to ozone

loss in several Chemistry–Climate Models. They find a wide range of sensitivity, even when differences in ozone and stratospheric temperatures are taken into account. Models with an equatorward bias in the climatology of the Southern Hemisphere jet stream appear more sensitive to stratospheric perturbations. A similar connection between jet shifts and climatological jet position was found in CMIP3 models (Kidston and Gerber 2010). These biases are associated with enhanced time scales of internal variability, providing a possible explanation through fluctuation–dissipation theory (Gerber et al. 2008; Ring and Plumb 2008).

Stratospheric impacts on Antarctica. A critical question at the frontier of climate prediction is how changes in the Southern Hemisphere atmospheric circulation may affect the Antarctic ice sheets. More rapid melting of the shelf is possible if comparatively warm ocean water is advected to the ice margin. The issue is thus how changes in surface wind stress over the Southern Ocean may affect ocean currents near Antarctica. A small-scale analogue has been studied in detail in the Northern Hemisphere, where changes in ocean circulation driven by natural variability of the jet stream associated with the North Atlantic Oscillation (NAO)² have accelerated the melting of the Jakobshavn Isbræ ice shelf on the western coast of Greenland (Holland et al. 2008). Whether stratospheric-induced wind changes in the Southern Hemisphere could similarly affect Antarctic ice sheets has profound implications for global sea level rise.

The stratosphere and geoengineering. Geoengineering, the deliberate modification of the Earth system to mitigate the effects of global warming, is also at the frontier of climate research. The injection of sulfate aerosols into the stratosphere has been proposed as a possible strategy of “solar radiation management.” The assumption is to replicate, enhance, and sustain the global cooling caused by volcanic eruptions to offset warming by greenhouse gases. A 2009 Royal Society report concluded that this option was potentially among the fastest and least expensive of known geoengineering strategies, but that it was also among the most dangerous in terms of the risk of unintended consequences (Shepherd et al. 2009). While there are growing concerns that microphysical processes, which control the scattering effectiveness and settling rate of aerosols, may limit the cost effectiveness of this strategy (e.g.,

² The trends in the NAO may have been in part driven by low-frequency variability in the stratosphere (Scaife et al. 2005).

Niemeier et al. 2011), the strong coupling between the stratosphere with other components of the Earth system alone suggests the need for great caution. The impact of stratospheric aerosols on ozone (Tilmes et al. 2008) and the fact that this mitigation strategy does nothing to stop ocean acidification are other strong causes for concern.

SUMMARY AND OPPORTUNITIES. There is conclusive evidence that the stratosphere plays a significant role in the natural variability and forced response of the Earth system. Better representation of the stratosphere can improve short-range forecasts and provide additional skill on seasonal time scales. Stratospheric ozone loss has played an important role in observed climate trends, in addition to its impact on UV radiation, and will continue to do so well into the twenty-first century. Exploration of the two-way interactions between the stratosphere and troposphere has also raised many questions. New research is required, both at the mechanistic level to piece together the subtle dynamical connections between stratospheric perturbations and tropospheric eddies, and at the global scale to build and assess models that capture all critical parts of the Earth system.

The emerging datasets of stratosphere-resolving models in the CMIP5 and Stratosphere Resolving Historical Forecast Project are a major step forward. They will enable us to better quantify the role of the stratosphere in the observed record and allow for unprecedented exploration of the stratosphere's role in future climate change. The SPARC DynVar activity is coordinating the investigation of these models by organizing research focus groups to assess particular stratospheric processes. Details can be found online (at www.sparcdynvar.org/research-topics-groups-folder/). A key goal for each group is to develop and refine existing metrics to better capture the influence of the stratosphere. Application of these metrics to models with different representations of stratospheric processes and dynamics is an important step in quantifying and understanding the role of the stratosphere in weather and climate.

While much of climate and weather research today justifiably focuses on building more comprehensive and sophisticated prediction systems, the area of stratospheric interactions is also ripe for conceptual work. There is a rich tradition of using simple models to explain and understand the workings of the atmosphere, particularly in the field of stratospheric dynamics. For example, a reduced model of the interaction between the stratospheric polar

vortex and tropospheric jet, along the lines of the Holton and Mass (1976) model of a single planetary wave interacting with a stratospheric jet, could provide a major advance in our understanding. There is also room for bold exploration. Just a few years ago, the claim that the halogenated compounds, which used to be contained within everyday aerosol spray cans, could move an entire storm track would have seemed rather preposterous. It is now speculative, but not unreasonable, to ask whether they might help melt an ice sheet. It took many years of dedicated research to link these halogenated compounds to ozone chemistry, ozone changes to stratospheric temperature changes, and stratospheric perturbations to tropospheric circulation anomalies. Will there be another link in the chain? These are exciting times for research on the coupling between the stratosphere and the Earth system.

ACKNOWLEDGMENTS. We thank Dr. Ben Ruston of the Marine Meteorology Division of the Naval Research Laboratory for permission to use the data in Fig. 2, and two anonymous reviewers for their comments on an earlier draft of the manuscript. EPG gratefully acknowledges the support of the National Science Foundation through the Atmospheric and Geospace Sciences program. FS acknowledges the support of the Office of Naval Research through NRL's base 6.1 and 6.2 research programs. JP's contribution is supported by NOAA's Climate Program Office, and MG and EM acknowledge the partial support of the COMBINE project of the European Commission's Seventh Framework Programme.

SEVERE CONVECTIVE STORMS

METEOROLOGICAL MONOGRAPH No. 50

Edited by Charles Doswell III

This volume is a collection of 13 review papers by a distinguished group of scientists, providing a summary of the current scientific understanding of convective storms and the weather they produce, as well as showing how that understanding works in forecasting practice. The volume is loaded with outstanding illustrations, and is destined to become one of the most widely referred-to books on convection and convective processes.

SEVERE CONVECTIVE STORMS, Meteorological Monograph No. 50

ISBN 1-878220-41-1, 576 pp., hardbound, \$110 list/\$90 member, student member price: \$75. To place an order, submit your prepaid orders to Order Department, AMS, 45 Beacon Street, Boston, MA 02108-3693; call 617-227-2425 to order by phone using Visa, Mastercard, or American Express; or send e-mail to amsorder@ametsoc.org. Please make checks payable to the American Meteorological Society.
